The development of the relativistic all-order method where all single, double, and partial triple excitations of the Dirac-Hartree-Fock wave function are included to all orders of perturbation theory led to many important results for study of fundamental symmetries, development of atomic clocks, ultracold atom physics, and others, as well as provided recommended values of many atomic properties critically evaluated for their accuracy for large number of monovalent systems. This approach requires iterative solutions of the linearized coupled-cluster equations leading to convergence issues in some cases where correlation corrections are particularly large or lead to an oscillating pattern. Moreover, these issues also lead to similar problems in the CI+all-order method for many-particle systems. In this work, we have resolved most of the known convergence problems by applying two different convergence stabilizer methods, reduced linear equation (RLE) and direct inversion of iterative subspace (DIIS). Examples are presented for B, Al, Zn⁺, and Yb⁺. Solving these convergence problems greatly expands the number of atomic species that can be treated with the all-order methods and is anticipated to facilitate many interesting future applications.

I. INTRODUCTION

The coupled-cluster (CC) method has been successfully applied to solve quantum many-body problems in quantum chemistry [1, 2] as well as computational atomic [3] and nuclear physics [4]. A relativistic linearized variant of the coupled-cluster method (which is numerically symmetric and is generally referred to as “all-order method”) was developed for atomic physics applications in Refs. [5–7]. It is one of the most accurate methods currently being used in the atomic structure calculations. This approach was extremely successful and led to accurate predictions of energies, transition amplitudes, hyperfine constants, polarizabilities, C₃ and C₆ coefficients, isotope shifts, and other properties of monovalent atoms, as well as the calculation of parity-nonconserving (PNC) amplitudes in Cs, Fr, and Ra⁺ (see [8–13] and references therein). Further development of the all-order approach, that included triple excitations and non-linear terms yielded the most precise evaluation of the PNC amplitude in Cs [14, 15] and consequent re-analysis of Cs experiment [16]. This work provided the most accurate low-energy test of the electroweak sector of the Standard Model to date, placed constraints on a variety of new physics scenarios beyond the SM, and, when combined with the results of high-energy collider experiments, confirmed the energy dependence (or “running”) of the electroweak force over an energy range spanning 10 MeV to 100 GeV. All-order method was also used for development of ultra-precise atomic clocks [17–21], ultracold atom and quantum information studies [22–26] and many other applications. We refer the reader to review [12] for details of the all-order method and its applications. The all-order method is also used as a part of the CI+all-order approach for study of more complicated systems [27].

The all-order method requires iterative solutions of the linearized coupled-cluster equations leading to convergence issues in some cases when correlation corrections are very large or produce an oscillating iterative pattern. The initial guess of the solution is based on the low-order perturbation theory. Therefore, if high-order correlation corrections are large, initial guess is very poor leading to very slow convergence or failure of the straightforward iterative scheme. In addition, initial non-linear CC equations may have more than one solution, so a convergence to non-physical solutions may occur. Several such problems have been identified over the years and led to failure to apply all-order approach for many important applications. For example, all or almost all of the low-lying nd and nf states of B, Al, Zn⁺, Cd⁺, Hg⁺, and Yb⁺ do not converge if standard Jacobi-type iterative procedure is applied. In the case of Yb⁺, even core equations do not converge. Convergence problems also cause complete failure of the all-order approach for super-heavy elements, such as element 113 (eka-Tl).

All these convergence issues in monovalent systems lead to the same problems in the application of the CI+all-order approach [27] to the corresponding divalent systems, such as Al⁺, Hg, Yb, etc. since this method required prior solution of LCCSD equations for one-particle orbitals. There are several interesting present applications of these atoms and ions that require high-precision calculations possible with all-order techniques. For example, several of these systems are used or proposed for optical clocks [17, 28–31] requiring precise knowledge of the blackbody radiation (BBR) shift which is hard to accurately measure. BBR shift is a leading source of uncertainties for many of the atomic clock schemes. Yb is used for an ongoing PNC experiment [32] as well as studies of degenerate quantum gases [33, 34] owing to a number of available isotopes. The best available Yb PNC...
amplitude value is only accurate to 20% [35].

The convergence issues that arise in the solutions of eigenvalue equations have a long history in general quantum chemistry and several methods have been developed to address them [36–42]. Most of these methods are based on the fundamental idea of effective reduction of original large functional space and solution of the projected to the reduced (Krylov) subspace of the simplified equations. This idea was implemented for the first time in a quantum chemical application by Lanczos [43], who facilitated a partial diagonalization of a large matrix by transforming to a much smaller Krylov subspace, followed by a matrix triangularization procedure.

In the present work, we consider two such convergence techniques, namely, reduced linear equation (RLE) [36, 37] and the direct inversion of iterative subspace (DIIS) [38, 39]. Both of the methods use approximate solutions obtained from few last iterations as Krylov reduced functional subspace onto which the linearized equations are projected and in which the projected system of equations is solved. The convergence of the methods is based on the construction of error vectors. Different choices of the error vectors lead to different implementation of the methods. Among the most popular error vectors are: 1) the difference of subsequent iterations and 2) “true” error vector (e.g. difference between exact solution and it's approximation). In our work, both the convergence methods use the same best least squares approximation to the true error vector and thus are rather relative. Moreover, our variant of DIIS can be regarded as a “symmetric” version of RLE (see below). However, while DIIS method is chosen to minimize the error vector in the least-squares sense, the RLE differs from it by requiring that this vector within the basis vanishes.

We formulate here implementations of the RLE and DIIS methods for our variant of the coupled-cluster equations and test these stabilizer methods on several specific examples, in which we were able to resolve the convergence problems listed above. We also studied the effectiveness of these two techniques in solving specific types of the convergence problems as well as accelerating convergence in all other cases. Acceleration of convergence is particularly important for further CI+all-order use since it requires solving all-order equations for a large number of one-particle orbitals.

Below, we briefly outline the essence of the convergence stabilization procedures. In the coupled-cluster method, the desired exact wave function \( |\psi\rangle \) is obtained by applying (a yet unknown operator) \( \exp(T) \) on some reference wave function \( |\phi\rangle \), for example, the Dirac-Hartree-Fock (DHF) wavefunction. For a closed-shell system with \( N \) electrons, the cluster operator \( T = \sum T_p \) (where \( p = 1, 2, 3, \ldots, N \)) has the form:

\[
T_p = 1/p! \sum_{mn,ab} \rho_{mn,ab} a_m^{\dagger} a_n^{\dagger} a_b a_a \tag{1}
\]

Here, orbitals \( m, n \) are single-particle excited states; \( a, b \) are core states which are occupied in \( |\phi\rangle \); \( \rho \)'s are cluster amplitudes (also called excitation coefficients) and \( a^{\dagger} \) and \( a \) are creation and annihilation operators with respect to the quasi-vacuum state \( |\phi\rangle \). Finally, \( p \) is the number of core electrons excited when applying \( T_p \) to \( |\phi\rangle \). In the linearized coupled-cluster single-double (LCCSD) method, only \( T_1 \) and \( T_2 \) are retained and non-linear terms in the expansion of \( \exp(T) \) are truncated. The LCCSD equations are conventionally solved by an iterative scheme, symbolically written as \( \rho^{(n-1)} = F(\rho^{(n)}) \), \( F \) being specified later in Section II. In this paper, this type of straightforward iteration procedure is referred to as the conventional iterations scheme (CIS).

Both RLE and DIIS convergence stabilization procedures form \( \rho^{(n-1)} \) solution as the linear combination of cluster amplitudes \( \rho^{(n)}, \rho^{(n-1)}, \ldots, \rho^{(n-1)} \) accumulated from \( l \) previous CIS iterations. Further details of the LCCSD method and RLE and DIIS schemes are discussed in Sections II and III.

An example of failed conventional iteration procedure is shown in Fig. 1, where we plot the LCCSD correlation energy, \( \delta E \), as a function of a number of valence LCCSD iterations for the 3s \( ^2S_{1/2} \) state of boron. Here and below we treat atoms as if they were monovalent systems. To streamline notation, we label many-electron states \( n\ell_j \) \( ^2S \) \( L_J \) simply as \( n\ell_j \) (since \( S = 1/2, L = \ell, \) and \( J = \ell \)). For example the 3s \( ^2S_{1/2} \) state of boron will be labeled as 3s. The experimental correlation energy (-0.0079754 a.u.) is indicated by the horizontal dashed line. It is computed by subtracting DHF energy from the experimental result. The LCCSD 3s correlation energy...
diverges from the experimental values dramatically and begins to oscillate after a number of iterations. The convergence criteria is set to terminate the iteration procedure when the relative difference between two consecutive iterations is reduced below 0.00001. The convergence is not reached even after 500 iterations. As demonstrated below, this problem is completely resolved by the use of either RLE or DIIS procedures and convergence to the above criteria is reached within 30 iterations.

This paper is organized as follows: in Section II, we describe the LCCSD method and the conventional iteration procedure (CIS) of solving the LCCSD equations. In Section III, we formulate RLE and DIIS schemes for LCCSD equations. In Section IV, we analyze performance of the RLE and DIIS schemes for various cases. Finally, in Section V, we draw the conclusions.

II. LINEARIZED SD COUPLED-CLUSTER METHOD

In the present implementation of the CC method, the exact valence wave function |ψv⟩ is obtained from the lowest-order DHF state,

|φv⟩ = a†v|0v⟩ ,

by applying a wave operator Ω = N[exp(T)] [3]; |

|ψv⟩ = Ω|φv⟩ ,

where |0v⟩ is the core DHF state and N[...] designates the normal product of operators with respect to a closed-shell core. Taking into account only the T1 and T2 terms in Eq. (1), and truncating Ω past the linear terms in the expansion of the exponential leads to the LCCSD ansatz for the wave operator

Ω ≃ 1 + ∑ mna ρmaa†ma + 1 2 ∑ mnab ρmnabba†maa†maa

+ ∑ m≠v ρmvba†ma

+ ∑ mna ρmnva†maa†maa a

= 1 + Sc + Dc + Sv + Dv. (4)

Here, Sc and Dc (Sv, Dv) are the core (valence) single and double terms, respectively.

To find the cluster amplitudes (or excitation coefficients) ρ, we need to specify the Hamiltonian. In our approach, we use the Hamiltonian [7] \( H = H_0 + G \):

\[ H = \sum_i \varepsilon_i N[a_i^\dagger a_i] + \frac{1}{2} \sum_{ijkl} g_{ijkl} N[a_i^\dagger a_j^\dagger a_k a_l], \]

where \( H_0 \) is the one-electron lowest-order DHF Hamiltonian and \( G \) is the residual Coulomb interaction. Indices \( i, j, k, \) and \( l \) range over all possible single-particle orbitals, and \( g_{ijkl} \) are the two-body Coulomb matrix elements. A set of coupled equations for the cluster operators \( (T_n) \):

\( (T_c)_1 = S_c, \ (T_v)_1 = S_v, \ (T_c)_2 = D_c, \) and \( (T_v)_2 = D_v \)

may be found from the Bloch equation [3]. For monovalent systems [44]:

\[ (\varepsilon_v - H_0)(T_v)_n = \{QGΩ\}_{\text{connected}, n}, \]

\[ (\varepsilon_v + \delta E_v - H_0)(T_v)_n = \{QGΩ\}_{\text{connected}, n}, \]

where \( \delta E_v = \langle \phi_v |GΩ|\phi_v \rangle \) is the valence correlation energy and \( Q = 1 - |\phi_v \rangle \langle \phi_v | \) is the projection operator. Note that Eq. (6) contains only the core cluster operators, while Eq. (7) contains both core and valence cluster operators. The core equations (6) are solved first, and the resulting CC core amplitudes are subsequently frozen and used in the valence equations (7).

The summations over the magnetic quantum numbers \( m \) in Eqs. (6) and (7) are performed analytically. After the angular reduction, the equation for the reduced single core cluster amplitudes \( \rho(ma) \) takes form [9, 45]:

\[ (\varepsilon_A - \varepsilon_m)\rho(ma) = \]

\[ \delta_{k\kappa}\left(\sum_{nb} \rho_{mban} \right) \]

\[ + \sum_{k} \left(1 - \delta_{jk}\right) Z_k(mban) \rho_{k(nmb)} \]

\[ + \sum_{k} \left(1 - \delta_{jk}\right) Z_k(mbrn) \rho_{k(rnab)}. \]

Here, \( [j] = (2j + 1, \kappa) \) is the relativistic angular momentum quantum number, \( \rho(ma) \) and \( \rho_{k(nmb)} \) are reduced single and double cluster amplitudes, \( X_k(mban) \) are reduced two-body Coulomb matrix elements, and

\[ Z_k(mban) = X_k(mban) \]

\[ + \sum_{k} [k] \left( j_m j_a j_b k \right) X_k(mnab). \]

The equations for the reduced double core cluster amplitudes \( \rho_k(mnab) \) are given by:

\[ (\varepsilon_{ab} - \varepsilon_{mn}) \rho_k(mnab) = X_k(mnab) \]

\[ + \sum_{cd} \sum_{l,k'} A_1 X_1(cdab) \rho_k'(mncd) \]

\[ + \sum_{rs} \sum_{l,k'} A_2 X_1(mnrs) \rho_k'(rsab) \]

\[ + \left[ \sum_{r} X_k(mnrb) \rho(ra) \delta_{k\kappa} \right] + \sum_{c} X_k(cnab) \rho(mc) \delta_{k\kappa} \]

\[ - \sum_{rc} \left(1 - \delta_{j_c j_r+k}\right) Z_k(cnrb) \rho_{k(mrac)} + \left[a \leftrightarrow b \right. \left.m \leftrightarrow n \right] \]

where \( A_1 \) are angular coefficients given in [45] and \( \varepsilon_{ij} = \varepsilon_i + \varepsilon_j \). The valence equations have exactly the same form as the core equations with the replacement of index \( a \) by the valence index \( v \) everywhere and an addition of the valence correlation energy \( \delta E_v \) into the energy difference.
on the left-hand side, i.e., \((\varepsilon_a - \varepsilon_m)p(ma) \rightarrow (\varepsilon_v - \varepsilon_m + \delta E_v)p(mv)\).

Implementation of the RLE and DIIS procedures requires rewriting the equations for the cluster amplitudes in a specific vector form. We introduce the vector notation:

\[
t = \begin{pmatrix} \rho(ma) \\ \rho_k(mnab) \end{pmatrix},
\]

where \(\rho(ma)\) and \(\rho_k(mnab)\) are to be understood as columns composed of all amplitudes for single and double excitations, respectively, i.e., for all possible values of \(m, n, a, b,\) and \(k\) indexes. Then, the core equations given by Eqs. (8) and (9) may be combined as

\[
D \cdot t = -a - \Delta \cdot t,
\]

where

\[
a = \begin{pmatrix} 0 \\ X_k(mnab) \end{pmatrix}, \quad D = \begin{pmatrix} \varepsilon_a - \varepsilon_m \\ \varepsilon_{ab} - \varepsilon_{mn} \end{pmatrix},
\]

and \(\Delta \cdot t\) includes all terms on the right-hand sides of the Eqs. (8) and (9) except for \(X_k(mnab)\), which is included in \(a\).

Valence equations may be written in the same way with

\[
t = \begin{pmatrix} \rho(mv) \\ \rho_k(mnv) \end{pmatrix},
\]

and

\[
a = \begin{pmatrix} 0 \\ X_k(mnv) \end{pmatrix}, \quad D = \begin{pmatrix} \varepsilon_v - \varepsilon_m + \delta E_v \\ \varepsilon_{vb} - \varepsilon_{mn} + \delta E_v \end{pmatrix}.
\]

The main difference between the core and valence equations for the implementation of the RLE and DIIS is the dependence of the valence array \(D\) on the iteration number, since \(\delta E_v\) is recalculated after every iteration. In the core case, \(D\) remains constant.

Solving Eq. (10) for \(t\) gives

\[
t = -D^{-1}(a + \Delta \cdot t).
\]

The above equation can be solved iteratively as

\[
t^{(m+1)} = -D^{-1}(a + \Delta \cdot t^{(m)}).
\]

The iteration usually starts by inserting \(t^{(0)} = 0\) on the right hand side of Eq. (12) and finding \(t^{(1)}\). As we demonstrated in Fig. 1, convergence of this straightforward iterative scheme is occasionally very slow or fails altogether. The convergence methods that we develop in the next section will alleviate such problems and lead to faster convergence rates.

### III. RLE AND DIIS

In this section, we formulate implementation of RLE and DIIS methods for the LCCSD equations (11) discussed in the previous section. Both methods are two-step procedures. In the first step, a few iterative solutions \(t^{(i)}\) of Eq. (12) are found (same as the CIS). In the second step, a linear combination of these \(t^{(i)}\) is used to find the next best solution of Eq. (12). The new answer is then used for another initialization of the CIS and the two steps are repeated until convergence to specified criteria is reached. In this section, we present the general RLE and DIIS formulas and derive their explicit form for the LCCSD equations.

After accumulating \(m + 1\) iteratively found solutions, \(t^{(1)}, t^{(2)}, ..., t^{(m+1)}\), next best approximation can be found as their linear combination,

\[
t^{[m+1]} = \sum_{i=1}^{m} \sigma_i t^{(i)} = \sigma \cdot T.
\]

The quantities \(\sigma_i\) are the weights that have to be determined by solving a system of equations constructed from previously found \(m + 1\) CIS solutions. We note that \(t^{(m+1)}\) is not included in the linear combination (13), but is used to find \(\sigma_i\) coefficients. Therefore, we use the notation \(t^{[m+1]}\) instead of \(t^{(m+1)}\) to distinguish between the \(m + 1\) solution found through the use of RLE/DIIS methods and the initial CIS result, respectively.

Both direct inversion of iterative space (DIIS) and reduced linear equation (RLE) methods seek to minimize the error between the iteratively found solutions of Eq. (11) and the exact answer. The error minimization is the basis for finding the appropriate \(\sigma_i\) to form the approximate solution \(t^{[m+1]}\). Both methods also use a least square approach to the error minimization. Since the exact answer is unknown, approximations are used in the minimization process. The approximate solution, as mentioned before, is constructed as a linear combination of a series of iteratively found solutions. The difference between the DIIS and the RLE methods is in the assumptions they make in order to minimize the errors. Further details of the difference between the two methods and derivations of the DIIS/RLE formulas can be found in the Appendix A.

We rewrite Eq. (10) as

\[
a + (\Delta + D)t = a + Bt = 0.
\]

The DIIS formula for determining \(\sigma_i\) is given by Eq. (A7):

\[
T^T B^T a + T^T B^T B T \sigma = 0.
\]

The RLE formula for determining \(\sigma_i\) is given by Eq. (A9):

\[
T^T (a + B T \sigma) = 0.
\]

Both Eqs. (15) and (16) can be written as a system of \(m\) equations:

\[
\alpha + R \sigma = 0.
\]
Next, we write \( \mathbf{R} \) and \( \mathbf{a} \) of Eq. (17) in their explicit forms for DIIS and RLE methods. Substituting \( \Delta - \mathbf{D} \) for \( \mathbf{B} \) into DIIS equation (15) yields for the \( \sigma_i \)

\[
t^T (\Delta + \mathbf{D})^T a + t^T (\Delta + \mathbf{D})^T (\Delta + \mathbf{D}) t^{(i)} \sigma_i = 0.
\]

Using Eq. (12), we find that \( \Delta \cdot t^{(i)} = -(\mathbf{D} \cdot t^{(i+1)} + \mathbf{a}) \). Replacing the dot products involving \( \Delta \) with ones involving \( \mathbf{D} \) yields explicit form of DIIS matrix for core orbitals

\[
R_{ij} = \sum_k D_{kk} a_k \left( t_k^{(i+1)} + t_k^{(j+1)} - t_k^{(i)} - t_k^{(j)} \right) + \sum_k (a_k)^2
+ \sum_k D_{kk}^2 \left( t_k^{(i)} t_k^{(j)} + t_k^{(i+1)} t_k^{(j+1)} - t_k^{(i)} t_k^{(j+1)} - t_k^{(i+1)} t_k^{(j)} \right)
\]

\[
\alpha_i = \sum_k a_k D_{kk} \left( t_k^{(i)} - t_k^{(i+1)} \right) - \sum_k (a_k)^2.
\]

The RLE equations for core orbitals are obtained by repeating the same steps as for the DIIS approach but starting from Eq. (16). The resulting RLE equations for \( \mathbf{R} \) and \( \mathbf{a} \) are

\[
R_{ij} = \sum_{kl} t_{kl}^{(i)} (\Delta_{kl} + D_{kl}) t_{kl}^{(j)}
= \sum_k \left[ t_k^{(i)} D_{kk} t_k^{(j)} - t_k^{(i)} D_{kk} t_k^{(j+1)} - a_k t_k^{(j)} \right],
\]

\[
\alpha_i = \sum_k \left[ t_k^{(i)} a_k \right].
\]

We noted in the previous section that \( \mathbf{D} \) depends on the correlation energy, \( \delta E_v \), in the case of the valence equations leading to the dependence of \( \mathbf{D} \) on the iteration number. Therefore, the substitution \( \mathbf{D} \rightarrow \mathbf{D}^{(i)} \) must be made to rewrite the DIIS and RLE equations above for the valence orbitals. To derive the final form of the equations, we have to introduce a somewhat arbitrary dot product and normalization definitions. The explicit form of the core RLE equations is obtained by substituting the expressions for \( \mathbf{D}, \mathbf{a}, \) and \( \mathbf{t} \) from the previous section into Eq. (19):

\[
R_{ij} = \sum_{ma} \left( \varepsilon_a - \varepsilon_m \right) \rho^{(i)}(ma) \left[ \rho^{(j)}(ma) - \rho^{(j+1)}(ma) \right]
+ \sum_{L \ mmba} \frac{1}{[L]} \left( \varepsilon_{ab} - \varepsilon_{mn} + \delta E_v^{(j)} \right) \rho_L^{(i)}(mnb)
\times \left[ \rho_L^{(j)}(mnb) - \rho_L^{(j+1)}(mnb) \right] - \alpha_i,
\]

\[
\alpha_i = -\sum_{L \ mmba} \frac{1}{[L]} X_L(mnb) \rho_L^{(i)}(mnb).
\]

IV. RESULTS AND DISCUSSION

In this section, we study and compare the convergence characteristics of the DIIS and the RLE methods. We include a number of test cases in four different systems,
TABLE I: Convergence tests of the LCCSD equations with CIS, RLE, and DIIS methods for B and Al. CIS is the conventional iterations scheme (no convergence stabilizer). RLE5 designates RLE convergence method with 5 pre-stored iterations. Last column gives resulting correlation energy in a.u. *Cases where maximum number of iterations allowed during run was reached.

B, Al, Zn$^+$, and Yb$^+$ which have a large number of states that do not converge with the conventional iterative scheme (CIS). We also test the ability of the RLE and the DIIS to accelerate convergence in the cases where the CIS does converge. The main purpose of these tests is to provide general guidelines of how to accelerate or to achieve convergence using the RLE and the DIIS methods. The conclusions and observations of this section may be extrapolated to other systems for both all-order and CI+all-order approaches.

The summary of B and Al convergence tests is given in Table I. We find that convergence patterns for two fine-structure multiplet states, for example 3p$_{1/2}$ and 3p$_{3/2}$ states, are generally very similar. Therefore, we list only np$_{1/2}$ and nd$_{3/2}$ states with the exception of the 4d states of Al. Tests were performed for both states of the multiplet as an additional check, since similar results are expected. The results are given for the 2p$_{1/2}$, 3p$_{1/2}$, and 3d$_{3/2}$ states of B and the 3p$_{1/2}$, 4s, 3d$_{3/2}$, 4d$_{3/2}$ and 4d$_{5/2}$ states of Al. The resulting LCCSD correlation energy is listed in the last column of the table in au. The convergence method is specified in the third column. CIS refers to the initial straightforward iteration scheme. RLE5 designates the RLE convergence method with 5 pre-stored CIS iterations. Similarly, DIIS8 refers to the DIIS convergence method with 8 pre-stored iterations. The fourth column indicates the iteration number at the end of the run. Cases where the maximum number of iterations allowed during the run was reached are marked with asterisk. In these cases, convergence did not occur. The convergence criteria was set to terminate the iteration procedure when the relative difference between two consecutive iterations is reduced below 0.00001. The same convergence criteria is used in all valence test runs. Only the core and the 2p states of B converge with the CIS. In the case of Al, all nd states do not converge with the CIS. All of the cases in Table I converge with the DIIS8. We note that we did not list the RLE5 and the DIIS5 results for many of the nd states because convergence was not achieved. In cases where all methods lead to convergence, both the RLE and the DIIS have accelerated convergence rates relative to the CIS.

![FIG. 3: (Color online) Comparison of the DIIS5, RLE8, and DIIS8 schemes for the 3d$_{3/2}$ state of boron. The correlation energy is given in a.u.](image-url)

We may draw two general conclusions from our tests:

1. If a particular LCCSD run converges with the CIS,....
then the RLE5 appears to be the most efficient method in accelerating the convergence.

2. If a particular LCCSD run does not converge with the CIS, the DIIS8 or the DIIS9 appear to be the most efficient in attaining and accelerating the convergence.

We note that these two rules are not absolute, but they serve to be good initial guidelines. Our further tests on other (much heavier) systems confirmed these guidelines. We note that the RLE5 is not sufficient to achieve convergence for most of the divergent cases. The only exception in Table I is the 3s state of B. However, while the CIS never converges to our standard criteria for the 3s state, it nearly converges to correct result before exhibiting diverging and oscillating pattern of Fig. 1. In this case, accumulation of only 5 iterations is sufficient. However, in the case of the nd states, the CIS is never close to converging to a correct number and subsequently the RLE5 does not work. Occasionally, DIIS9 may achieve convergence where DIIS8 would not. Using even larger number of stored iterations does not improve convergence or efficiency. DIIS10-DIIS12 runs for the 4d states converged to non-physical answers in two instances, but to correct results in all other cases. Number of iterations varied significantly from case to case. The results of all converged runs listed in Table I are consistent within the convergence criteria, as expected.

We implemented the DIIS/RLE strategies for two separately developed LCCSD codes. The calculations were carried out using two different finite basis sets, the B-splines of Ref. [46] and the dual-kinetic-basis sets of Ref. [47]. Even though the basis sets and the convergence criteria used for each code made slight differences in the values, the general observations on the convergence patterns remains the same.

We illustrate different convergence patterns of the RLE and the DIIS methods for the 3s and 3d3/2 states of boron in Figs. 2 and 3. In Fig. 2, the values of the correlation energies for the 3s states of boron are obtained from different schemes that are listed on the graph. RLE5, DIIS5, and DIIS7 results after N = 20 interactions are indistinguishable at this point scale and are not shown. These schemes converge after 30, 22, and 31 iterations, respectively. While the CIS results appear close to converged value, convergence was never reached and correlation energy began to oscillate as illustrated in Fig. 1. The RLE5 and the DIIS5 results are identical to the CIS ones for the first four iterations. The 5th value is different for three of the schemes as this (m + 1)-th value (see Eq. (13)) is replaced by the RLE or the DIIS predictions for RLE5 and DIIS5. We observe that these predictions are significantly closer to converged result than the 5th CIS iteration. After that, the RLE5 and DIIS5 results are sharply adjusted at N = 10 when the second call to the RLE/DIIS stabilizer codes is made. The DIIS7 behavior is similar to the one just described, except that it accumulates 7 iterations before the DIIS procedure is invoked and now the 7th value gets much closer to the final answer.

In Fig. 3, the values of the correlation energies obtained from CIS, DIIS5, RLE8, and DIIS8 are plotted for the 3d3/2 states of boron. The RLE8 and the DIIS8 results after N = 35 appear identical on the graph at this scale and are not shown. The RLE8 and the DIIS8 converge to our criteria after 66 and 51 iterations, respectively. Very similar behavior of the RLE8 and the DIIS8 is observed, with the RLE8 energy oscillations being slightly larger after the RLE subroutine pass. However, other tests show that the RLE8 in general converges slower, sometimes dramatically so, than the DIIS8. The CIS values diverge completely and increase rapidly. The DIIS5 seems to be converging at N = 35, but does not in fact reach selected criteria even after 100 iterations.

The summary of the selected Zn and Yb convergence tests is presented in Table II. The results are given for the 5p1/2, 4d3/2, 4d5/2, and 3d3/2, 4f5/2, and 4f7/2 states of Zn and the Yb core. The 4s and 4p3 states of Zn and the 6s, 6p3, 7s, and 5d3 states of Yb converge with the CIS, so we have omitted these results from the table. However, it is worth pointing out that RLE5 accelerates convergence for all these states compared to the CIS. Table II demonstrates that the DIIS reduces num-

FIG. 4: (Color online) Comparison of the CIS, RLE5, and DIIS5 schemes for the Yb\(^+\) core. The correlation energy is given in a.u. RLE5 and DIIS generate identical results with the single core. Both methods are successful at fixing the CIS's oscillation problem.

The comparison of the B, Al, Zn\(^+\), and Yb\(^+\) removal energies with experiment [48] is given in Table III. Rows labeled “Dif.” give relative difference with experimental values in %. The energies here are given in cm\(^{-1}\). Most of these states did not converge with the CIS, so it is important to establish the accuracy of this approach for such cases. Breit interactions and contributions from higher partial waves are also included. The B and Al ionization potentials, B 2\(p_{3/2}\), and Al 4s SD energies are in agreement with experiment. We consider only monovalent states for all of these systems. The SD approximation does not account for mixing with the core-excited states such as 3\(s^3p^2\) in Al. Therefore, larger disagreement with experiment is expected in cases where mixing with these hole-two-particle states is large. A particular example is the 3\(d\) and 4\(d\) states of Al. The lower 3\(s^2nd\) levels heavily mix with the 3\(s^3p^2\) 2\(D\) levels. However, the mixing coefficient for this configuration never exceeds 30%. As a result, these levels are distributed over several lower \(nd\) levels, resulting in two sets of levels being listed as 3\(s^24d\) \(2D\) [48, 49] ([3\(p^2\)2\(D\)]). In Table III, we compare the 4\(d\) results with the second sets of levels ([3\(p^2\)2\(D\)]).

We also included partial valence triples perturbatively
(LCCSDpT) to investigate if the LCCSDpT method would improve the theory-experiment agreement for Zn$^+$ and Yb$^+$. This method is described in detail in [9]. Since triple equations are not explicitly iterated in this approach, implementation of the RLE and the DIIS method is exactly the same as in the SD code. Convergence tests of the LCCSDpT method exhibit essentially the same pattern as the tests of the LCCSD method discussed above, and a similar number of iterations was generally required for LCCSD and LCCSDpT calculations for the same states run with the same parameters.

As shown in Table III, we find an excellent agreement of all Zn$^+$ data with experiment. Inclusion of perturbative triples somewhat improves the agreement with experiment for most states. The accuracy decreases for Yb$^+$, as expected, owing to much softer and heavier core and strong mixing of monovalent states with one-hole-two-particle states in this system. Nevertheless, for Yb$^+$ the average accuracy for removal energies is at the level of 1% (see Table III.)

V. CONCLUSION

We have successfully implemented the RLE and DIIS convergence techniques in the LCCSD and LCCSDpT methods for high-precision atomic many-body calculations. Most of the convergence problems were resolved using these methods. Acceleration of convergence was demonstrated for all cases where all-order equations converge with straightforward iteration scheme. Numerous tests were performed to establish general recommendations for the RLE/DIIS use for various purposes. We find that if particular case converges with CIS, RLE5 appears to be the most efficient in achieving and accelerating convergence. If particular case does not converge with CIS, DIIS5 or DIIS9 appear to be the most efficient in accelerating convergence. Solving these convergence problems greatly expands the number of atomic species that can be treated with the all-order methods and is anticipated to facilitate many interesting future applications for studies of fundamental symmetries as well as atomic clock and ultracold atom research.

Appendix A

Derivations of general formulas in this Appendix mainly follows Appendix of Ref. [36]. Consider solving a general linear equation of the form

$$\mathbf{a} + \mathbf{Bt} = 0, \quad (A1)$$

which is a system of linear equations of dimension $k$ with vector $\mathbf{t}$ being the exact solution that we would like to find. We make the best approximation to the exact solution by using $m(<k)$ nonorthogonal and linearly independent vectors $\mathbf{T} = (\mathbf{t}^{(1)}, \mathbf{t}^{(2)}, ..., \mathbf{t}^{(m)})$, where each $\mathbf{t}^{(i)}$ is a $k$-dimensional vector. We find this best approximation as a linear combination of $\mathbf{t}^{(i)}$'s:

$$\mathbf{t}^{(m+1)} = \sum_{i=1}^{m} \sigma_i \mathbf{t}^{(i)} = \sigma \cdot \mathbf{T}. \quad (A2)$$

Here, $\sigma_i$ are the weights of the optimized solution that needs to be determined. We note that $\mathbf{t}^{(m+1)}$ is not included in the linear combination (A2), but is used to construct matrices such as shown in Eqs.(20) and (21). Therefore, $\mathbf{t}^{(m+1)}$ needs to be also found through the CIS. Therefore, we use the notation $\mathbf{t}^{(m+1)}$ instead of $\mathbf{t}^{(m+1)}$ to distinguish between the $m + 1$th solution found through the use of RLE/DIIS methods and the CIS result, respectively.

First, we try to derive an ideal equation to find $\sigma_i$’s as if we knew the exact solution to Eq. (A1). To find the best approximation, we need to minimize the error between the approximate and the exact answers. To this end, we use the least square optimization approach. The error is $\mathbf{e} = \mathbf{t} - \mathbf{t}^{(m+1)}$. The least square optimization of $E = \mathbf{e}^T \mathbf{e}$ with respect to $\sigma$ then yields

$$\frac{\partial E}{\partial \sigma} = -2 \mathbf{T}^T (\mathbf{t} - \mathbf{T} \cdot \sigma) = 0. \quad (A3)$$

After solving for $\sigma$ and substituting it in Eq.(A2), we get

$$\mathbf{t}^{(m+1)} = \mathbf{T}(\mathbf{T}^T \mathbf{T})^{-1} \mathbf{T}^T \mathbf{t}. \quad (A4)$$

However, not knowing what the exact solution $\mathbf{t}$ is, the above formula is of little use. The DIIS and RLE are based on replacing $\mathbf{t}$ with approximations. Substituting $\mathbf{t}^{(m+1)}$ instead of $\mathbf{t}$ in Eq.(A1), will make Eq.(A1) inhomogeneous:

$$\mathbf{a} + \mathbf{Bt}^{(m+1)} = \mathbf{a} + \mathbf{BT} \cdot \sigma = \mathbf{e}. \quad (A5)$$

where $\mathbf{e}$ is a vector with constant elements.

The difference between the RLE and DIIS methods is in their choice of error to minimize, $\mathbf{e}$. The DIIS takes the error to be $\mathbf{e}$ of Eq. (A5). Then to get the best approximation, we need to minimize $E = \mathbf{e}^T \mathbf{e}$ with respect to $\sigma$:

$$\frac{\partial E}{\partial \sigma} = 2(-\mathbf{BT})^T (\mathbf{a} + \mathbf{BT} \sigma) = 0. \quad (A6)$$

Therefore, the coefficients $\sigma$ that lead to the best approximation satisfy the DIIS equation:

$$\mathbf{T}^T \mathbf{B}^T \mathbf{a} + \mathbf{T}^T \mathbf{B}^T \mathbf{B}^T \sigma = 0. \quad (A7)$$

The RLE requires that the best least square approximation $\mathbf{e}^{(m+1)}$ to $\mathbf{e}$ vanishes in the space of $\mathbf{T}$. Following the structure of Eq. (A4):

$$\mathbf{e}^{(m+1)} = \mathbf{T}(\mathbf{T}^T \mathbf{T})^{-1} \mathbf{T}^T \mathbf{e} = \mathbf{T}(\mathbf{T}^T \mathbf{T})^{-1} \mathbf{T}^T (\mathbf{a} + \mathbf{BT} \sigma) = 0. \quad (A8)$$
Since $\mathbf{T}$ is made of linearly independent vectors, $\epsilon^{[m+1]}$ is only zero if:

$$\mathbf{T}^T(\alpha + \mathbf{B}\mathbf{T}\sigma) = 0. \quad (A9)$$

Eqs. (A7) and (A9) for DIIS and RLE, respectively, correspond to Eqs. (15) and (16) in the paper.
