(Dated: March 21, 2012)

Quantum spin networks can be used to transport information between separated registers in a quantum information processor. To find a practical implementation, the strict requirements of ideal perfect state transfer models need to be relaxed, allowing for complex coupling topologies and general initial states. Here we analyze transport in complex quantum spin networks in the maximally mixed state and derive explicit conditions that should be satisfied by propagators for perfect state transport. Using a description of the transport process as a quantum walk over the network, we show that it is necessary to phase correlate the transport processes occurring along all the possible paths in the network. We provide a Hamiltonian that achieves this correlation, and use it in a constructive method to derive engineered couplings for perfect transport in complicated network topologies.

I. INTRODUCTION

In the quest toward a scalable quantum computer [1], a promising model comprises distributed computing units connected by passive wires that transmit quantum information [2–6]. This architecture would provide several advantages, since the wires require no or limited control, easing the fabrication requirements and improving their isolation from the environment. For a simpler integration in a solid-state architecture, the wires can be composed of spins. Following seminal work by Bose [7], which showed that spin chains enable transporting quantum states between the ends of the chain, the dynamics of quantum state transfer has been widely studied (see Ref. [8] for a review), and protocols for improving the fidelity by coupling engineering [9–16], dual-rail topologies [17], active control on the chain spins [18] or on the end spins only [19–22] have been proposed. Recently these studies have been extended to mixed state spin chains [23–27], which are more easily obtained in high-temperature laboratory settings – making them important protagonists in practical quantum computing. A further challenge to experimental implementation of quantum transport is the lack of chains with the desired coupling strengths, since coupling engineering is limited by fabrication constraints and by the presence of long-range interactions. These challenges highlight the need for a systematic study of mixed state transport in quantum systems beyond chains, including more complex network topologies. These topologies reflect more closely actual experimental conditions as well as systems occurring in nature. For example, there is remarkable recent evidence [28, 29] that coherent quantum transport may be the underlying reason for the high efficiency (of over 99%) of photosynthetic energy transfer [30].

To derive explicit conditions for perfect transport we quantify geometric constraints on the unitary propagator that drives transport in an arbitrary network. As a consequence, we find that transferring some mixed states in a network in general requires fewer conditions than pure state transfer. Transport conditions for pure states have been previously quantified [31], however, our method – relying on decomposing the propagator in orthogonal spaces – is fundamentally different and more suitable for mixed states.

Perfect transport occurs when the bulk of the network acts like a lens to focus transport to its ends. To make this physical picture more concrete, we describe mixed state transport as a continuous quantum walk over the network [32–34] which progressively populates its nodes. Through this formalism, we derive constructive conditions on the coupling Hamiltonian that results in the correlation of transport processes through different possible paths in the network. The correlation of transport processes leads to their constructive interference at the position of the two end-spins, giving perfect transport. While similar walk models have been applied to coherent transport before (see [35] for a review), our work provides their first extension to transport involving mixed states.

The insight gained by describing quantum transport as correlated quantum walks can be used to construct larger networks where perfect transport is possible. Here we show a strategy to achieve this goal by engineering the coupling strengths between different nodes of the network to construct weighted spin networks that support perfect mixed state transport. Feder [36] had considered a similar problem for pure states by mapping the quantum walk of \( N \) spinor bosons to a single particle; this has been extended in more recent work [37–39]. Here we find far more relaxed weighting requirements for mixed state transport, thanks in part to a fermionic instead of bosonic mapping. In turn, this could ease the fabrication requirements for coupling engineering.

The paper is organized as follows. In Sec. II we define
the problem of mixed state transport. Sec. III provides
the geometric conditions on the propagator for perfect
transport in arbitrary networks. We finally present in
Sec. IV the quantum walk formalism, which allows the
correlation of transport processes over different paths
and the construction of families of weighted networks
that support perfect transfer.

II. TRANSPORT IN MIXED-STATE NETWORKS

Consider an $N$-spin network $\mathcal{N}$, whose vertices (nodes)
$V$ represent spins and whose edges $E = \{\alpha_{ij}\}$ describe
the couplings between spins $i$ and $j$ (see Fig. 1). The
system dynamics is governed by the Hamiltonian $H = \sum_{i<j} \alpha_{ij} H_{ij}$, where $H_{ij}$ is the operator form of the
interaction. In the most general case, a spin of $N$
state $\rho$ coupled to several others, for instance, in a dipolar cou-
pled network, $\alpha_{ij} \sim 1/r_{ij}^3$ is a function of the distance
between the spins in the network.

We assume that we can identify two nodes, labeled 1
and $N$, that we can (partially) control and read out, in-
dependently from the "bulk" of the network, and thus
act as the "end" spins between which transport will oc-
cur. The rest of the spins in the network can at most
be manipulated by collective control. This also imposes
restrictions on the network initialization [24–26]. To re-
 lax the requirements for the network preparation, we as-
sume to work in the infinite-temperature limit [25] – a
physical setting easily achievable for many experimen-
tal systems – where the bulk spins are in the maxi-
mally mixed state, $\rho \propto I$. We will then consider the
transport of a slight excess polarization from node 1 to
node $N$. The initial state is $\rho_1 \sim (I + \delta Z_1)$, where
$Z_1$ is the Pauli matrix acting on spin 1 and $\delta \ll 1
$ denotes the polarization excess. Since only the trace-
less part of the density matrix evolves in time, we will
monitor the transport from $\rho_1^\Delta = Z_1$ to a desired final
state $\rho_2^\Delta = Z_N$. The fidelity of the transport process
is then defined as $F(t) = \text{Tr}(\rho^\Delta(t) Z_N)/\text{Tr}(Z_N^\dagger Z_1)$, with
$\rho^\Delta(t) = U(t) \rho^\Delta U^\dagger(t)$ being the evolved state.

The polarization behaves like a wave-packet traveling
over the network $\mathcal{N}$ [40, 41]. In most cases, the Hamilton-
ian $H$ drives a rapidly dispersive evolution, where the
wave-packet quickly spreads out into many-body corre-
lations among the nodes of $\mathcal{N}$, from which it cannot be
recovered [34]. This is for example the case of evolution
under the naturally occurring dipolar Hamiltonian, which
induces a fast-decay of the polarization as measured in solid-state NMR, even if many-body corre-
lations can be detected at longer times [42].

In order to drive a dispersionless transport, thus en-
suring perfect fidelity, the network Hamiltonian should
satisfy very specific conditions. In this paper we will
investigate these conditions by answering the questions:
(i) What are the possible operator forms of the Hamilton-
ian $H_{ij}$ for dispersionless transport? (ii) What are the
coupling topologies and (iii) strengths $\alpha_{ij}$ that support
perfect transport?

III. CONDITIONS FOR PERFECT TRANSPORT

A. Fidelity of mixed-state transport

The condition for perfect transport, $F = 1$, can be ex-
pressed in a compact form by using the product-operator
(PO) basis [43]. For the $N$-spin network system there are
$2^{2N}$ basis elements,

$$\mathbf{B} = \mathbf{B}_1 \otimes \mathbf{B}_{\text{bulk}} \otimes \mathbf{B}_N = \{ 1, X_1, Y_1, Z_1, X_2, \ldots, X_1, X_2, \ldots, Z_1 Z_2, X_1 X_2 X_3, \ldots, Z_1 Z_2 \cdots Z_{N-1} Z_N \},$$

where $\mathbf{B}_1, \mathbf{B}_N$ and $\mathbf{B}_{\text{bulk}}$ are the basis for the end and the
bulk spins, respectively.

Using the PO basis, the propagator $U(t) = e^{-i H t}$ can be rep-
resented by a vector $| U \rangle = \begin{pmatrix} c_{B_1}, c_{B_2}, \ldots, c_{B_{2N}} \end{pmatrix}^T$ in the $2^{2N}$ dimensional Hilbert-Schmidt (HS) operator spanned by $\mathbf{B}$ [44]:

$$U(t) = \sum_i c_{B_i}(t) B_i, \quad \text{with} \quad c_{B_i} = \frac{\text{Tr}(B_i^\dagger U)}{\text{Tr}(B_i^\dagger B_i)}$$

From an initial state with a polarization excess on spin 1,
$\rho_1^\Delta = Z_1$, the system evolves to

$$\rho_2^\Delta = U \rho_1^\Delta U^\dagger = \sum_{ij} c_{B_i} c_{B_j}^* B_i Z_1 B_j,$$

yielding the transport fidelity to spin $N$

$$F = \frac{1}{\text{Tr}(Z_1^\dagger Z_1)} \text{Tr} \left[ \sum_{i,j} c_{B_i} c_{B_j}^* B_i Z_1 B_j Z_N \right] = \sum_{ij} c_{B_i} c_{B_j}^*,$$

with $B_j = \pm Z_1 Z_N B_i$, for $[B_i, Z_N]_F = 0.$

The last equation follows from the property that all ele-
ments of $\mathbf{B}$, except $I$, are traceless.
The fidelity derived in Eq. (3) has a simple form in the HS space. Note that in this operator space, the product $B_i U$ is a linear transformation, $T : |U⟩ → \hat{P}_{B_i}|U⟩$, where $\hat{P}_{B_i}$ is a permutation matrix corresponding to the action of $B_i$ [44] (here and in the following we denote operators in the HS space by a hat). The unitarity of $U$ yields the conditions:

$$||U|| = ⟨U|U⟩ = 1 \quad ⟨U|\hat{P}_{B_i}|U⟩ = 0, \quad B_i \neq 1.$$  \hspace{1cm} (4)

Let us partition the HS space in two subspaces $G$, $\tilde{G}$, spanned by the basis $G$ and $\tilde{G}$,

$$G = B_1 \otimes B_{\text{bulk}} \otimes \{1, Z_N\}, \quad \tilde{G} = B_1 \otimes B_{\text{bulk}} \otimes \{X_N, Y_N\},$$

and note that all elements of $G$ commute with $Z_N$, while all elements of $\tilde{G}$ anti-commute with $Z_N$. We will label by superscripts $\tilde{G}$ and $\tilde{G}$ the projections of operators in these subspaces. Using this partition, we can simplify the expression for the fidelity of Eq. (3) to obtain

$$F = ⟨U|\hat{P}_{Z_1Z_N}\hat{P}_R|U⟩,$$  \hspace{1cm} (5)

where $\hat{P}_R$ is a reflection about $G$ and $\hat{P}_{Z_1Z_N}$ is block-diagonal in the $\{G, \tilde{G}\}$ basis (since $Z_1Z_N \in \tilde{G}$):

$$\hat{P}_R = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}, \quad \hat{P}_{Z_1Z_N} = \begin{bmatrix} \hat{P}_{\tilde{G}} & 0 \\ 0 & \hat{P}_{\tilde{G}} \end{bmatrix}.$$  \hspace{1cm} (6)

Rewriting the fidelity as the inner product between two vectors, $F = ⟨⟨(\hat{P}_{Z_1Z_N}|U⟩)|\hat{P}_R|U⟩$, provides a simple geometric interpretation of the perfect transport condition, as shown in Fig. 2. The vector $\hat{P}_{Z_1Z_N}|U⟩$ should be parallel to $\hat{P}_R|U⟩$, which can be obtained if $\hat{P}_{Z_1Z_N}$ rotates $|U\tilde{G}\rangle$ by an angle $\pi$, while leaving $|U\tilde{G}\rangle$ unaffected. Alternatively, since $\hat{P}_{Z_1Z_N}$ just describes the $\pi$-rotation of the vector $|U⟩$ about the $Z_1Z_N$ axis, for perfect transport the rotation-reflection operation $S = \hat{P}_{Z_1Z_N}\hat{P}_R$ should be a symmetry operation for $|U⟩$.

From Eq. (4) we have $⟨U|\hat{P}_{Z_1Z_N}|U⟩ = 0$ and using Eq. (5) we can derive explicit conditions to be satisfied by the propagator to achieve perfect transport, $F = 1$

$$\langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle + \langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle = 0$$

$$\langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle - \langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle = 1$$

that simplify to

$$\langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle = -\langle U\tilde{G}|\hat{P}_{\tilde{G}}|U\tilde{G}\rangle = \frac{1}{2}.$$  \hspace{1cm} (9)

When is this equation satisfied? By symmetry, it happens when $||U\tilde{G}|| = ||U\tilde{G}|| = 1/2$, and $|U\tilde{G}\rangle$ and $|U\tilde{G}\rangle$ are (up to a phase) eigenvectors of $\hat{P}_{\tilde{G}}$ and $\hat{P}_{\tilde{G}}$ with eigenvalues $\pm 1$ respectively:

$$\hat{P}_{\tilde{G}}|U\tilde{G}\rangle = +|U\tilde{G}\rangle; \quad \hat{P}_{\tilde{G}}|U\tilde{G}\rangle = -|U\tilde{G}\rangle.$$  \hspace{1cm} (10)

To enable perfect transport, $|U⟩$ must thus have an equal projection on the two subspaces $G$ and $\tilde{G}$, as shown geometrically in Fig. 2. Also, intuitively from the symmetry operation $S$, all components of $|U⟩$ lying on the plane $G$ should be rotationally symmetric with respect to $Z_1Z_N$, while components of $|U⟩$ lying on the plane $\tilde{G}$ should have reflection symmetry about $Z_1Z_N$.

Note that Eq. (10) imposes fairly weak constraints on the transport unitaries, as opposed to the constraints for pure state transport [31, 45]. In particular Eq. (10) provides no explicit constraint on the bulk of the network. For example, the two propagators,

$$U_1 = B_{\text{bulk}}(1 \pm Z_1Z_N) + B_{\text{bulk}}(X_1X_N \mp Y_1Y_N),$$

$$U_2 = B_{\text{bulk}}(1 \pm Z_1Z_N) + B_{\text{bulk}}(X_1Y_N \mp Y_1X_N),$$  \hspace{1cm} (11)

with $B_{\text{bulk}}$ and $B_{\text{bulk}}$ arbitrary operators ($\in \text{span}\{B_{\text{bulk}}\}$) acting on the bulk, support perfect transport. Other propagators can be obtained thanks to an invariance property that we present in the next section. More generally, in Appendix A we explicitly provide a prescription to construct classes of unitaries for perfect mixed state transport.

### B. Invariance of transport Hamiltonians

The fidelity $F$ in Eq. (3) is invariant under a transformation $U' = VU$, where $V$ is unitary and commutes with $S$, that is,

$$[V, \hat{P}_{Z_1Z_N}\hat{P}_R] = 0.$$  \hspace{1cm} (12)

This invariance can be used to construct Hamiltonians that support perfect transport starting from known ones. Consider an Hamiltonian $H$ that generates the transport
evolution \( U = \exp(-i H t) \). Then the transport driven by \( H \) is identical to that generated by the Hamiltonian \( H' = VHV \), where \( V \) satisfies Eq. (12).

Ref. [46] proved similar symmetry requirements for Hamiltonians that transport pure states; here, however, we derived these Hamiltonian properties just from the geometric conditions on \( U \). Ref. [47] treated a similar problem, defining classes of Hamiltonians that perform the same action on a state of interest. A special case of this result was used in [23] to study transport in a mixed-state spin chain driven either by the nearest-neighbor coupling isotropic XY Hamiltonian,

\[
H_{XY} = \sum_i \alpha_i T^+_{i+1} \text{ with } T^+_{ij} = (S^+_i S^-_j + S^-_i S^+_j)
\]

or double-quantum (DQ) Hamiltonian

\[
H_{DQ} = \sum_i \alpha_i D^+_{i+1} \text{ with } D^+_{ij} = (S^+_i S^-_j + S^-_i S^+_j)
\]

with \( S^\pm_i = \frac{1}{2}(X_i \pm i Y_i) \). The unitary operator relating the two Hamiltonians, \( V = \prod_k X_k \), where the product \( k' \) extends over all even or odd spins, does indeed satisfy Eq. (12).

C. Quantum information transport via mixed state networks

The requirements for perfect transport (Eq. (10)) can be easily generalized to the transport between any two elements of \( B \), say from \( \mathcal{I} \) to \( \mathcal{F} \). One has simply to appropriately construct the subspaces \( \mathcal{G} \) and \( \mathcal{G} \) and the corresponding permutation operator \( \tilde{P}_{\mathcal{I}X} \).

One could further consider under which conditions this transport (for example, \( X_1 \to X_N \)) can occur simultaneously with the \( Z_1 \to Z_N \) transport already considered. More generally, the simultaneous transfer of operators forming a basis for \( \mathcal{B}_1 \) would enable the transport of quantum information [10, 25] via a mixed-state network. The unitary \( U \) should not now only be symmetric under \( \tilde{S} \), but should also under a similar operator derived for \( X_1 X_N \). The requirements on \( U \) thus become more stringent and only a special case of the propagators constructed in Eq. (A3) in Appendix A is allowed,

\[
U = B_{\text{bulk}} (\mathbb{I} \pm Z_1 Z_N + X_1 X_N \pm Y_1 Y_N).
\]

This is exactly a SWAP operation (up to a phase) between the end-spins, which can also lead to a transfer of arbitrary pure states between 1 and \( N \). Therefore, we find that perfect transport of non-commuting mixed states between the end-spins also allows transport in pure state networks. We note that quantum information could be encoded in multi-spin states [25, 48] that satisfy proper symmetry conditions and thus do not impose additional conditions on the transport propagators.

D. Which Hamiltonians support mixed state transport?

It would be interesting to determine which Hamiltonians can generate propagators \( |U(t)\rangle = \exp(-i H t) \mathbb{I} \) for perfect transport. Unfortunately, deriving requirements for the Hamiltonian from the conditions on the unitaries is non-trivial; however, as we show below, one can still extract useful information.

A general Hamiltonian can be decomposed as \( H = H^G + H^G \), where \( H^G, \tilde{G} \) lie in the subspaces \( \mathcal{G} \) and \( \tilde{G} \), respectively. We cannot set \( H = H^G \) since the Hamiltonian does need to have a component that is non-commuting with the target operator \( |Z_N\rangle \) in order to drive the transport. If \( H = H^G \), odd powers of \( H \) are in \( \tilde{G} \), while even powers of \( H \) belong to \( \mathcal{G} \). Then the propagator has contributions from \( |U^G\rangle \) and \( |\tilde{U}^G\rangle \) with

\[
|U^G\rangle = |\mathbb{I}\rangle + \frac{(it)^2}{2!} \hat{H} |H\rangle + \frac{(it)^4}{4!} \hat{H}^3 |H\rangle + \cdots
\]

\[
|\tilde{U}^G\rangle = it |H\rangle + \frac{(it)^3}{3!} \hat{H}^2 |H\rangle + \cdots
\]

We can demonstrate that in this case the Hamiltonian must satisfy two conditions to drive perfect transport. First, the “vector” form of the Hamiltonian must be an eigenstate of \( \tilde{P}_{Z_1 Z_N} |H\rangle = -|H\rangle \), which ensures that the second equation in (10) is trivially satisfied, as

\[
\tilde{P}_{Z_1 Z_N} |\tilde{U}^G\rangle = -|U^G\rangle.
\]

Second, since we have

\[
\tilde{P}_{Z_1 Z_N} |U^G\rangle = |Z_1 Z_N\rangle + \frac{(it)^2}{2!} \hat{H} |H\rangle + \frac{(it)^4}{4!} \hat{H}^3 |H\rangle + \cdots,
\]

the first equation in (10) implies that \( \hat{H}^{2n} = \frac{1}{2}(\mathbb{I} - Z_1 Z_N) \) for any \( n \).

These conditions are for example satisfied by the XY-like Hamiltonian, \( H = B_{\text{bulk}} T^+_{1N} \), where \( B_{\text{bulk}} \) is any operator acting on the bulk and \( T^+_{1N} = (S^+_1 S^-_N \pm S^-_1 S^+_N) \). In this case, at \( t = \pi/4 \), all conditions in Eq. (10) are satisfied and perfect transport is achieved. Indeed the XY Hamiltonian has been widely studied for quantum transport [7, 9] and it is interesting that we could derive its transport properties solely by the symmetry conditions on the propagator.

An Hamiltonian \( H = H^G \) with support only in \( \tilde{G} \) is however a very restrictive case as it refers to the situation where all nodes of the network are connected to \( N \). Hamiltonians with support in both subspaces are more experimentally relevant, as they correspond to a common physical situation, where the ends of the network are separated in space and direct interaction between them is zero or too weak. In the following, we will consider this more general situation, although restricting the study to XY Hamiltonians in order to derive conditions for perfect transport.
IV. PERFECT TRANSPORT IN NETWORKS: CORRELATED QUANTUM WALKS

In the following, we will consider the network $\mathcal{N}$ to consist of spins that are coupled by XY-like interaction, $\{T_i^+\}$. We focus on this interaction since it has been shown that with appropriate engineered coupling strengths, $\alpha_{ij} \propto \sqrt{i(N-i)}\delta_{j,i+1}$, the XY-Hamiltonian can support perfect transport in linear chains (see e.g. [10–12, 49]). Thanks to the invariance property described in Sec. IIIIB, this analysis applies to a much broader class of Hamiltonians, in particular to the DQ Hamiltonian.

We assume that the end spins of $\mathcal{N}$ are not directly coupled, thus transport needs to be mediated by the bulk of the network. The simplest such topology is a $\Lambda$-type configuration where the end spins are coupled to a single spin in the bulk. The Hamiltonian $\Lambda_j = (T_{ij}^+ + T_{jN}^+)/\sqrt{2}$, where $j$ is a spin in the bulk, is enough to drive this transport. In this case, $(\Lambda_j^2)^n = \Lambda_j^2 \forall n$, and hence the propagator is

$$U = \exp(-i Ht) = \mathbb{1} + [\cos(t) - 1]H^2 - i \sin(t) H,$$  \hspace{1cm} (17)

where $H^2 = 1/2[(T_{ij}^+)^2 + (T_{jN}^+)^2 + T_{1N}^+]$. Since $(\mathbb{1} - 2H^2)$ has the form of $U_3$ in Eq. (A3), setting $t = \pi$ ensures $U = U_3$, yielding perfect transport. This is an expected result, since this simple lambda-network is just a 3-spin linear chain. This result can be extended to longer chains, as long as engineered couplings ensure that the resulting Hamiltonian is mirror-symmetric [10, 16, 45].

A different situation arises when there is more than one transport path possible, that is, the end spins are coupled to more than one spin in the bulk with an Hamiltonian $H = \sum_{j \in \text{bulk}} \alpha_j \Lambda_j$. For example, Fig. 3 depicts a network similar to the one considered in [26, 50] where there are three $\Lambda$-paths between the end-spins. Even if each path individually supports perfect transport, evolution along different paths may not be correlated, leading to destructive interference reducing the fidelity (see Fig. 3).

Perfect fidelity can be achieved only if different paths can be collapsed into a single “effective” one that supports perfect transport (Fig. 3). This strategy not only allows us to determine if an Hamiltonian can support perfect transport, but it also gives a recipe to build allowed Hamiltonians, by combining simpler networks known to support perfect transport into more complex ones.

To this end, we use the fact that linear chains enable perfect transport with appropriate engineered couplings. Our first step will then be to give conditions under which two chains of the same length (with end-spins in common) can be combined. To obtain these conditions, we describe the evolution of the spin polarization as a quantum walk over the operators in the network [33, 34]. This description reveals the need to correlate the parallel paths over the network, in order to achieve a constructive re-focusing of the polarization at the other end of the network. We then generalize the conditions by a recursive construction to quite general networks.

![Diagram](image.png)

**FIG. 3.** (Color online) (a) $\Lambda$-type network with three $\Lambda$ paths between the bulk and end-spins and equal coupling strength $\alpha$. (b) Transport fidelity as a function of normalized time for the $\Lambda$-network coupled by the XY-Hamiltonian $T_{ij}^+$ (blue dashed) and the modified XY-Hamiltonian $\tilde{T}_{ij}^+$ (red solid). In the latter case, correlated quantum walks lead to perfect transport.

A. Transport as a quantum walk over $\mathcal{N}$

We describe the transport evolution as a quantum walk over the network, which progressively populates operators in the HS space. We first expand the transport fidelity $F(t)$ (Eq. 5) in a time series,

$$F(t) = \langle \mathbb{1} | \hat{P}_{Z_{iN}} \hat{P}_{R} | U_0 \rangle - it \langle U_0 \left| [\hat{H}, \hat{P}_{Z_{iN}} \hat{P}_{R}] \right| U_0 \rangle + \frac{t^2}{2!} \langle U_0 \left| [\hat{H}, [\hat{H}, \hat{P}_{Z_{iN}} \hat{P}_{R}]] \right| U_0 \rangle + \cdots$$  \hspace{1cm} (18)

with $| U_0 \rangle = | \mathbb{1} \rangle$. This process of progressively populating different parts of the HS space upon continuous time evolution under the Hamiltonian can be considered as a quantum walk [33, 34, 51]. Defining the nested commutators,

$$C_0 = \hat{P}_{Z_{iN}} \hat{P}_{R} ; \quad C_n = [\hat{H}, C_{n-1}],$$  \hspace{1cm} (19)

Eq. (18) takes the form

$$F(t) = \sum_{n=0}^{\infty} \frac{(it)^n}{n!} \langle C_n \rangle,$$  \hspace{1cm} (20)

where the expectation value is taken with respect to $| U_0 \rangle$.

A large part of the Hamiltonian commutes with $\hat{P}_{Z_{iN}} \hat{P}_{R}$ and can be neglected. We can isolate the non-commuting part by defining the operator $\hat{A}$ via the relationship

$$[\hat{H}, \hat{P}_{Z_{iN}} \hat{P}_{R}] = \hat{A} \hat{P}_{Z_{iN}} \hat{P}_{R}. \quad \hspace{1cm} (21)$$

The operator $\hat{A}$ and its nested commutators $C_n^A = [\hat{H}, C_n^A]$ (with $C_0^A = \hat{A}$) have a simple graphical construction. The commutation relations,

$$[T_{ij}^+, T_{jk}^+] = -Z_j T_{ik}^+, \quad [T_{ij}^+, T_{kl}^+] = 0,$$  \hspace{1cm} (22)
The commutator between two top legs (blue) of the directed graph is the third edge (red). In case of the XY Hamiltonian, the commutator is conditioned on node $j$. (see Fig. 4) can be used to provide a simple prescription to graphically determine the flip-flop terms in $C_n^A$. For any two edges, one in $C_{n-1}^A$ and one in $H$, that share a common node, $C_n^A$ contains the edge required to complete the triangle between them. Thus, each higher order in the commutation expansion creates a link between nodes in the network, progressively populating it. We will refer to the operators $C_n^A$ as quantum walk operators, since as we show below, the nested commutators $C_n$ in Eq. (20) can be built exclusively out of them.

Consider the network of Fig. 5(a), with coupling strengths $\alpha_{ij} = 1$: Â contains only the edges of $N$ that connect to node 1, as represented by the red lines in Fig. 5(b). Fig. 5(c-d) represent the higher order commutators, with a red line linking two nodes denoting a term $T_{ij}^+$ between them. We note that the graphical construction only predicts the presence of a flip-flop term $T_{ij}^+$ linking two nodes in the commutator $C_n^A$, while the explicit forms of the commutators is generally more complex, as shown in Table I, with additional appropriate weights for arbitrary coupling strengths $\alpha_{ij}$. Still, as we now show, only the $T_{ij}^+$ terms are important to determine the fidelity, and the presence of a $T_{ij}^+$ term in the graphical series is an indication that transport can occur between the end-nodes.

The commutators $C_n$ can indeed be written in terms of the $C_n^A$ nested commutators,

$$C_n = \sum_{k=0}^{n-1} \binom{n-1}{k} C_{n-1-k}^A C_k,$$  \hspace{1cm} (23) 

yielding an expression for the fidelity containing only products of the nested commutators $C_n^A$.

$$C_n = \sum_{k_1=0}^{n-1} \sum_{k_2=0}^{k_1-1} \cdots \sum_{k_n=0}^{k_{n-1}-1} \binom{n-1}{k_1} \binom{k_1-1}{k_2} \cdots \binom{k_{n-1}-1}{k_n} C_{n-k_1-k_2-\cdots-k_n}^A \hat{P}_{Z_i} Z_N \hat{P}_R.$$  \hspace{1cm} (24) 

For a commutator $C_n$ to yield a non-zero contribution to the fidelity, the product of the operators $C_n^A$ should be proportional to $Z_j^2$, that is, it should evaluate to even powers of $T_{ij}^+$. Hence very few terms appearing in $C_n$ actually contribute to the transfer fidelity $F$.

The geometric construction of $C_n^A$ only yields the XY operators contained in each commutator, but it does not reflect the appearance of prefactors $\propto Z_j$ (due to the
commutator in Eq. (22)) that are explicitly written out in Table I. Thus, the geometric construction gives a necessary condition for transport, but not a sufficient one.

The operators $C_n^A$ describe the sum of walks over different paths: for example in $C_3^A$, $Z_2 Z_3 T_{1N}^+$ can be interpreted as the information packet reaching node $N$ through path $P_1$ in Fig. 5(a), while $Z_4 Z_5 T_{1N}^-$ represents propagation via path $P_2$. These two terms could in principle contribute to the fidelity, as they contain prefactors, which are absent if the modified XY Hamiltonian is used. This allows for the correlation of transport through parallel paths.

Table I. Nested commutators $C_n^A$ (walk operators) corresponding to the graphs in Fig. 5 if the edges represent the XY Hamiltonian or the modified XY Hamiltonian. In the first case, note the presence of path dependent $Z_j$ prefactors, which are absent when the modified XY Hamiltonian is used.

Note that when the network $\mathcal{N}$ is a simple linear chain with nearest-neighbor couplings the modified Hamiltonian $T_{ij}^+$ is equivalent to the bare XY Hamiltonian. The modification in Eq. (25) of the XY-Hamiltonian could also be seen as mapping the spin system into a set of non-interacting fermions via a Jordan-Wigner transformation, where $C_i = \prod_{\alpha < \beta} Z_{\alpha} S_{\beta}^+$ are operators that satisfy the usual fermionic anti-commutation relationships. When these modified operators are employed in the network $\mathcal{N}$ of Fig. 5(a), the two paths $P_1$ and $P_2$ in Fig. 5(a) are indistinguishable or, equivalently, they become perfectly correlated (see Table I). In effect, the modified XY Hamiltonian drives the quantum walks over different paths through a common set of operators of $\mathcal{B}$. This is shown in Fig. 6 for a simple $\Lambda$-network consisting of two $\Lambda$ paths.

B. Correlating quantum walks over $\mathcal{N}$: Modified XY-Hamiltonian

To remove the path-conditioning one should modify the Hamiltonian so that the $Z_j$ term in the commutator $[T_{ij}^+, T_{jk}^-]$ disappears. This can be done via a modified XY-Hamiltonian

$$\tilde{T}_{ij}^\pm = T_{ij}^\pm \prod_{i < u < j} Z_u$$

since it satisfies this condition:

$$[\tilde{T}_{ij}^+, \tilde{T}_{jk}^-] = -\tilde{T}_{ik}^- ; \quad [\tilde{T}_{ij}^+, \tilde{T}_{ki}^-] = 0$$

These operators now depend on the number of nodes between $i$ and $j$, thus introducing a metric in the spin-space that distinguishes paths between the two nodes $i$ and $j$.

FIG. 6. (Color online) Operators appearing in the quantum walk of a network consisting of two $\Lambda$ paths, 1 $\rightarrow$ 2 $\rightarrow$ $N$ and 1 $\rightarrow$ 3 $\rightarrow$ $N$. In panel (a), where the transport is driven by the XY-Hamiltonian, the two paths through spins 2 and 3 are different, as they traverse a different set of operators, and are thus depicted in two separated grey panels. In panel (b), where we consider the modified XY Hamiltonian, both walks go through a common set of operators. The previously separate walks are bridged by the operators in the red box, making both walks indistinguishable and hence correlated.
Engineered spin networks

The graphic construction used to calculate the transport over the network in Fig. 5 remains unchanged, except that now the red lines between two nodes denote modified flip-flops $T_{ij}^{\pm}$ between them. Crucially there are no path dependent prefactors and symmetric nodes in each path become equivalent in each of the operators $C_n^A$. It is then possible to collapse different paths into a single effective one, until a complex network $N$ is collapsed into a linear chain. This is depicted in Fig. 7(a).

We can express this result more formally, by defining collapsed XY operators, where we denote in parenthesis equivalent nodes in two parallel paths:

$$\tilde{T}_{ij}^{\pm} = \frac{1}{\sqrt{\gamma_{ij}} + \gamma_{ik}} \left( \gamma_{ij} \tilde{T}_{ij}^{\pm} + \gamma_{ik} \tilde{T}_{ik}^{\pm} \right),$$

where $\gamma_{ij}$ and $\gamma_{ik}$ are arbitrary parameters, $0 < \gamma_{ij}, \gamma_{ik} < 1$ (see also Appendix B). Remarkably, these operators satisfy the same path-independent commutation relations as in Eq. (26)

$$[\tilde{T}_{ij(k)}^{\pm}, \tilde{T}_{(j,k)}^{\pm}] = -\tilde{T}_{ij}^{\pm},$$

thus showing that intermediate equivalent nodes can be neglected in higher order commutators. In addition the nested commutators $C_n^A$, and the graphical method to construct them (Fig. 4), remain invariant when substituting the modified XY operator with the collapsed operators $\tilde{T}_{ij}^{\pm}$.

Using the collapsed operators, the network of Fig. 5(a) can thus be reduced to a simpler linear chain (Fig. 7). Analogous arguments for path-collapsing were presented in [58], and have been applied before to some classes of graphs [9, 38]. In the following we show that path-equivalence could be constructed even for more complex network topologies, since, as we described, path collapsing can be derived just from the commutation relationships between the edges of the network.

C. Engineered spin networks

The path collapsing described in the previous section provides a constructive way to build networks, with appropriate coupling geometries and strengths, that achieve perfect transport. Alternatively, given a certain network geometry, the method determines all the possible coupling strength distributions that leave its transport fidelity unchanged.

For example, starting from a linear chain, any node can be substituted by two equivalent nodes, thus giving rise to two equivalent paths. Then, within the subspace of the equivalent nodes, the couplings can be set using Eq. (27) with arbitrary weights $\gamma$, thus giving much flexibility in the final allowed network. The engineered network corresponding to Fig. 5(a) is represented in Fig. 7(a), where equivalent nodes from $P_1$ are weighted by $\gamma$, while those from $P_2$ are weighted by $\sqrt{1 - \gamma^2}$.

A more complex example is shown in Fig. 7(b), where the network is built combining the networks in Fig. 3(a) and Fig. 5(a). It consists of three paths and can be collapsed into a 4-spin linear chain. The couplings shown lead to perfect $Z_1 \rightarrow Z_N$ transport for arbitrary path weights $\gamma_1$ and $\gamma_2$, with $0 < \gamma_1, \gamma_2 < 1$, as shown in Fig. 7(c). The network engineering scheme can be recursively integrated to construct larger and more complicated network topologies (see for example Fig. 8).

Similar weighted networks have been consider before for bosons [36]. The engineered couplings derived by mapping quantum walks of $N$ spinor bosons to the walk of a single particle are however much more restricted than what we found here via the mapping of spins to non-interacting fermions.
V. CONCLUSIONS AND OUTLOOK

Experimental implementation of quantum information transport requires relaxing many of the assumptions made in ideal schemes. In this paper we analyzed a physical situation that is closer to experimental settings – information transport in mixed-state spin networks with complex topologies. We first derived general conditions on propagators that allow perfect transport in these mixed-state spin networks. We used the conditions on the propagators to show that there exist classes of symmetry transformations on the Hamiltonians driving the transport for which the transport fidelity is invariant. We also showed that the propagator conditions also imply that transporting some mixed states requires fewer control requirements than pure state transport, an added advantage to using mixed-state channels in quantum information architectures.

In order to study quantum transfer in complex spin networks, we described the dynamics as a continuous quantum walk over the possible paths offered by the network. This description provided a graphical construction to predict the system evolution, which highlighted the need of correlating the transport processes occurring along different paths of the network to obtain perfect transport. We thus introduced a modified XY-Hamiltonian, based on Jordan-Wigner fermionization, that achieves correlation among paths by establishing a metric for the quantum walks occurring on the network. Conversely, the graphical construction could be as well used to study the generation from the usual XY-Hamiltonian of states of interest in measurement-based quantum computation [59].

Finally, the quantum-walk picture and the graphical construction lead us to define a constructive method to build complex networks from simpler ones, with appropriate coupling geometries and strengths, that achieve perfect transport. We thus found that there is considerable freedom in the choice of topology and interaction strength that still allows perfect transport in complex networks. While the requirement of a well-defined network topology could be further relaxed [60], the precise construction proposed in this paper would provide faster transport and the freedom in the coupling distributions made these networks implementable in experimental systems.

Appendix A: Constructing perfect transport unitaries

Here we show how the conditions specified in Eq. (10) could be used to construct perfect transport propagators. Our motivation for this is to demonstrate that the conditions of Eq. (10) are very weak, in the sense that is possible to construct an infinite classes of unitaries that support $Z_1 \rightarrow Z_N$ transport.

Consider the matrix forms of $\hat{P}^{g}_{Z_1 Z_N}$ and $\hat{P}^{g}_{Z_1 Z_N}$ in the two-dimensional $\{1, N\}$ subspace of $\mathcal{G}$ and $\tilde{\mathcal{G}}$:

$$\mathcal{G} \sim \left\{ \{1, Z_1 Z_N\}, \{Z_1, Z_N\}, \{X_1, Y_1 Z_N\}, \{Y_1, X_1 Z_N\}\right\}$$

$$\tilde{\mathcal{G}} \sim \left\{ \{X_1 X_N, Y_1 Y_N\}, \{X_1 Y_N, Y_1 X_N\}, \{X_N, Z_1 Y_N\}, \{Y_N, Z_1 X_N\}\right\} \quad (A1)$$

where the $\sim$ refers to the restriction in the $\{1, N\}$ subspace. Then, for this order of basis, the matrix forms are block diagonal

$$\hat{P}^{g}_{Z_1 Z_N} = \text{diag}([X, X, -Y, Y])$$

$$\tilde{\hat{P}}^{g}_{Z_1 Z_N} = \text{diag}([-X, -X, Y, Y]) \quad (A2)$$

where X and Y are the standard Pauli matrices, whose eigenvectors with eigenvalues $\pm 1$ are respectively $[1, \pm 1]^T$ and $[1, \pm i]^T$; this imposes a restriction on $U$. If $B_{\text{bulk}}, B'_{\text{bulk}} \in \text{span}\{B_{\text{bulk}}\}$, one can explicitly list from Eq. (10) possible forms of $U$ for perfect transport,

$$U_1 = B_{\text{bulk}}(1 \pm Z_1 Z_N) + B'_{\text{bulk}}(X_1 X_N \pm Y_1 Y_N),$$

$$U_2 = B_{\text{bulk}}(1 \pm Z_1 Z_N) + B_{\text{bulk}}(X_1 Y_N \mp Y_1 X_N),$$

$$U_3 = B_{\text{bulk}}(Z_1 \pm Y_1 Z_N) + B'_{\text{bulk}}(X_1 X_N \pm Y_1 Y_N),$$

$$U_4 = B_{\text{bulk}}(Z_1 \pm Z_N) + B_{\text{bulk}}(X_1 Y_N \mp Y_1 X_N),$$

$$U_5 = B_{\text{bulk}}(X_1 \pm i Y_1 Z_N) + B'_{\text{bulk}}(X_1 X_N \mp i Z_1 Y_N),$$

$$U_6 = B_{\text{bulk}}(X_1 \pm i Y_1 Z_N) + B'_{\text{bulk}}(X_1 Y_N \pm i Z_1 Y_N),$$

$$U_7 = B_{\text{bulk}}(Y_1 \pm i X_1 Z_N) + B_{\text{bulk}}(X_1 Y_N \pm i Z_1 Y_N),$$

$$U_8 = B_{\text{bulk}}(Y_1 \pm i X_1 Z_N) + B'_{\text{bulk}}(X_1 Y_N \mp i Z_1 X_N), \quad (A3)$$
Note that the bulk of the network specified by $B_{\text{bulk}}$ and $B_{\text{bulk}}^{-1}$ can be in any arbitrary state. In fact, the invariance described in Sec. IIIB could be used to show that the eight forms of $U$ in Eq. (A3) are equivalent to $U_1$ or $U_2$.

Of course, one can combine the forms in Eq. (A3) to form larger propagators that continue to support perfect transport. Consider for example a propagator constructed out of $U_1$ and $U_2$ in Eq. (A3), with $B_{\text{bulk}}, B_{\text{bulk}}^{-1} = \mathbb{1}$

$$U = \lambda_1 (1 \pm Z_N) + \lambda_2 (X_1 X_N \pm Y_1 Y_N) + \lambda_3 (X_1 Y_N \mp Y_1 X_N)$$

where $\lambda_j$ are coefficients to be determined. Then, from Eq. (4) we have

$$\langle U | U \rangle = 1 \Rightarrow |\lambda_1|^2 + |\lambda_2|^2 + |\lambda_3|^2 = 1$$

$$\langle U | P_{Z_N} | U \rangle = 0 \Rightarrow |\lambda_1|^2 = |\lambda_2|^2 + |\lambda_3|^2$$

$$\langle U | P_{X_N} | U \rangle = 0 \Rightarrow \text{Im}(\lambda_2 \lambda_3) = 0$$

(A4)

Other conditions in Eq. (4) are satisfied trivially. Eq. (A4) can be solved exactly; for example $\lambda_j = (1/\sqrt{2}, 1/2, 1/2)$ is a solution. Importantly however, if $B_{\text{bulk}}$ and $B_{\text{bulk}}^{-1}$ were different from each other, the set of equations Eq. (A4) becomes far simpler.

In summary, achieving $Z_1 \rightarrow Z_N$ transport requires weak conditions on the propagator driving the transport. This is as opposed to perfect pure state transport, that requires the propagators to be isomorphic to permutation operators [31] that are mirror symmetric [45] about the end spins of the network.

Appendix B: Properties of flip-flop and double-quantum Hamiltonians

In this appendix, we present simple relations satisfied by the flip-flop (XY) operators that will be used in the main paper. Note that the double-quantum (DQ) operators in Eq. (14) follow analogous equations. In what follows, distinct indices label distinct positions on the spin network unless otherwise specified. We start with the definition of the operators $S$ and $E$:

$$E_j^\pm = \frac{1}{2} (\mathbb{1} \pm Z_j), \quad S_j^\pm = \frac{1}{2} (X_j \pm i Y_j).$$

(B1)

These operators satisfy the following product rules:

$$Z_j S_j^\pm = \pm S_j^\pm, \quad (S_j^\pm)^2 = E_j^\pm E_j^\mp = 0,$$

$$S_j^\pm S_j^\mp = (E_j^\pm)^2 = E_j^\pm.$$  

(B2)

We define the flip-flop operators $T_{ij}^\pm$ and $L_{ij}^\pm$:

$$T_{ij}^\pm = (S_i^+ S_j^- \mp S_i^- S_j^+) \quad \text{and} \quad L_{ij}^\pm = (E_i^+ E_j^- \mp E_i^- E_j^+)$$

(B3)

From the definition in Eq. (B3) it follows that

$$T_{ij}^\pm = \pm T_{ji}^\mp \quad \text{and} \quad Z_j T_{ij}^\pm = T_{ij}^-.$$  

We have then the following product relations:

$$(T_{ij}^\pm)^2 = \pm L_{ij}^+, \quad T_{ij}^\pm L_{ij}^+ = L_{ij}^+ T_{ij}^\pm, \quad (L_{ij}^\pm)^2 = L_{ij}^+, \quad T_{ij}^\pm T_{jk}^\mp = \frac{1}{2} (T_{ik}^\mp - Z_j T_{ik}^\pm)$$

(B4)

and the commutation relations:

$$[T_{ij}^\pm, T_{jk}^\mp] = -Z_j T_{ik}^\mp, \quad [T_{ij}^\pm, Z_i] = T_{ij}^\mp; \quad [T_{ij}^\pm, T_{ij}^-] = -2T_{ij}^-.$$

(B5)

We define the modified flip-flop operators $\tilde{T}_{ij}^\pm$,

$$\tilde{T}_{ij}^\pm = T_{ij}^\pm \prod_{i < u < j} Z_u.$$  

(B6)

obtained by multiplying the flip-flop operator in Eq. (B3) by a factor of $Z_u$ for all nodes between $i$ and $j$. The modified flip-flop operators follow especially simple commutation rules

$$[\tilde{T}_{ij}^+, \tilde{T}_{jk}^+] = 0$$

(B7)

Note that crucially, these commutators only depend on the initial and final nodes $(i$ and $k)$, and are independent of intermediate nodes. In a physical analogy, the modified operators $\tilde{T}_{ij}^\pm$ behave as if they were path independent. Thus, when considering two (or more) paths, we could omit any intermediate node, since it would not enter in the ensuing commutators. We then denote equivalent nodes in parenthesis—for example, $(j, k)$ means nodes $j$ and $k$ are equivalent— and define the collapsed operators:

$$\tilde{T}_{(i,j,k)}^\pm = \frac{1}{\sqrt{\gamma_{ij} \gamma_{ik}}} \left( \gamma_{ij} \tilde{T}_{ij}^\pm + \gamma_{ik} \tilde{T}_{ik}^\pm \right).$$

(B8)

where $\gamma_{ij}, \gamma_{ik}$ are arbitrary parameters, $0 < \gamma_{ij}, \gamma_{ik} < 1$. The collapsed operators satisfy commutation relations similar to Eq. (B7):

$$[\tilde{T}_{(i,j,k)}^+, \tilde{T}_{(j,k)}^+] = -\tilde{T}_{ik}^+, \quad [\tilde{T}_{(i,j,k)}^+, \tilde{T}_{(i)}^+] = -\tilde{T}_{(i)}^+,$$

$$[\tilde{T}_{(j,k)}^+, \tilde{T}_{(j,k)}^+] = -\tilde{T}_{(j,k)}^+.$$  

(B9)

The collapsed operators in Eq. (B8) can be generalized. If $I = (a_1, a_2, \cdots, a_m)$ and $J = (b_1, b_2, \cdots, b_n)$ denote two sets of equivalent nodes, we have the collapsed operator

$$\tilde{T}_{IJ}^\pm = \frac{1}{\sqrt{\sum_{i=1}^{m} \sum_{j=1}^{n} \gamma_{a_i b_j} \gamma_{a_i b_j}}} \sum_{i=1}^{m} \sum_{j=1}^{n} \gamma_{a_i b_j} \tilde{T}_{a_i b_j}^\pm,$$  

(B10)

which satisfies the commutation relationships:

$$[\tilde{T}_{IJ}^+, \tilde{T}_{JK}^+] = -\tilde{T}_{IK}^+, \quad [\tilde{T}_{IJ}^+, \tilde{T}_{KL}^+] = 0.$$  

(B11)
