#### Abstract

We have experimentally observed two missing lowest vibrational levels of $\mathrm{Cs} 20_{g}^{-}$purely longrange states. The photoassociation spectroscopy of ultracold cesium atoms with rotational structure presents clear identification of missing lowest levels. Values of radiative lifetimes $\tau_{3 / 2}=30.41 \pm$ 0.06 ns and $\tau_{1 / 2}=34.81 \pm 0.07 \mathrm{~ns}$ of the $6 p^{2} P_{1 / 2}$ and $6 p^{2} P_{3 / 2}$ atomic levels and van der Waals coefficient $C_{6}=6852 \pm 25$ a.u. of ground state cesium molecule are extracted, respectively.

Research on cold and ultracold molecules received large attention in the last decade due to important advances and potentially new application in several domains like quantum computing [1], few body physics and physical chemistry [2]. The techniques that have produced up to now molecules in the ultracold temperature range mainly are magnetoassociation (MA) [3] and photoassociation (PA) [4]. PA spectroscopy of ultracold atoms has become a powerful tool for investigation of the so-called long-range molecules with classical outer turning points of several to hundreds nanometers. In the long-range molecules, properties of the molecular states are closely related to properties of their constituent atoms. A special class of long-range molecules is called a purely long-range (PLR) molecule. It has a classical inner turning point at a long internuclear distance where the short-range interaction due to the overlap of atomic electron clouds is negligible.

The spin-orbit coupling causes an avoided crossing between attractive and repulsive potentials correlating to different asymptotes. With increasing precision of the experiments, highly sensitive detection methods have brought significant progress in the domain of precision measurements for the PLR cesium molecule $\left(\mathrm{Cs}_{2}\right)$, for instance, resonant four-body interaction in cold cesium Rydberg atoms [5], absolute frequency stabilization to cesium atom molecular hyperfine transitions [6], the $C_{6}$ and $a_{T}$ values of $\mathrm{Cs}_{2}$ obtained in Ref. [7]. In these ultracold $\mathrm{Cs}_{2}$ experiments, the double-well structure of the $0_{g}^{-}$ molecular state correlated to the $6 S_{1 / 2}+6 P_{3 / 2}$ dissociation limit is a key feature in the process of forming ultracold molecules. The reliable description of this state is crucial, as the double-well structure of the PLR $0_{g}^{-}$state appears as a suitable intermediate step in the course of the formation of ground state molecules in their absolute ground state [8]. Photoassociation spectroscopy of $\mathrm{Cs}_{2}$ $0_{g}^{-}$PLR state had been obtained by Pillet et al. using ionization detection technique in 1999 [9]. Another feasible technique to directly detect the excited molecular state levels is trap-loss detection by monitoring the fluorescence yield from the trapped atoms described by M. Pichler et al. [10]. In these pioneering experiments, they
obtained the "lowest" vibrational level $v^{\prime}=0$ in $\mathrm{Cs}_{2} 0_{g}^{-}$ state by directly observation until the vibrational series broken off. The PA spectroscopy of PLR $0_{g}^{-}$state of ultracold $\mathrm{Cs}_{2}$ has been theoretically interpreted by Olivier Dulieu et al. [11, 12]. They provided a precision analytical expression for the external well of the $0_{g}^{-}$potential curve and convinced atomic lifetimes. It is very important to note that Dulieu and co-workers predicted two levels energetically below the "lowest" level $v^{\prime}=0$. However, such two missing lowest levels have not been experimentally observed so far, since the overlap between the two missing lowest levels states with the triplet ground state wave function is expected to be very small and it is difficult to observe the PA lines of missing levels with a very low intensity $[11,12]$. If these two missing lowest levels exist, the pioneering lowest vibrational level $v^{\prime}=0$ is actually $v=2$, numerous experimental and theoretical studies which based on $0_{g}^{-}$vibrational levels, besides, spectroscopy and potential curve should be modified [68, 13].

In this paper, we report the experimental observation of the missing lowest levels of ultracold PLR cesium molecules by carrying out three-dimensional modulation PA spectroscopy. Resolved ro-vibrational spectra of the PLR $0_{g}^{-}\left(6 P_{3 / 2}\right)$ state are obtained. The bound energy data of missing lowest levels are compared to theoretical predictions. We represent the potential curve with these new data by an analytical asymptotic approach. Values of the radiative lifetimes of the $6 p^{2} P_{1 / 2}$ and $6 p^{2} P_{3 / 2}$ atomic levels and van der Waals coefficient $C_{6}$ of ground state are obtained.

The details of the experimental setup have been schematically depicted in [6]. The sample of ultracold atoms was produced in a standard vapor-loaded ${ }^{133} \mathrm{Cs}$ magneto-optical trap (MOT) [14]. The trapping and repumping laser frequencies were locked to the Cs atomic transition $6 S_{1 / 2}(F=4) \rightarrow 6 P_{3 / 2}\left(F^{\prime}=5\right)$ and $6 S_{1 / 2}(F=3) \rightarrow 6 P_{3 / 2}\left(F^{\prime}=4\right)$, respectively. Fig.1(a) shows the formation and modulation scheme of photoassociative Cs molecules in the $0_{g}^{-}\left(6 P_{3 / 2}\right)$ state. The PA laser excites a pair of colliding Cs atoms into a PLR state. Ground state $\left(a^{3} \Sigma_{u}^{+}\right)$molecules are formed from these
excited molecules followed by spontaneous decay from the $0_{g}^{-}$state. In PA experiments, the response time of the MOT is usually rather slow ( $\sim 1 \mathrm{~s}$ ), thus it requires slow scanning rate of the PA laser frequency. Therefore, a fast and effective modulation of the number of trapped cold atoms is difficult. We employ a coupling laser as an independent modulation medium in order to controllably modulate the fluorescence of the trapped atoms [14, 15]. The coupling laser beams, provided by a diode laser, are introduced into the center of MOT strictly along the directions of the trapping laser beams. For sine wave modulation, the instantaneous frequency of the coupling laser is $v(t)=v_{0}-m \cos (2 \pi \omega t)$, where $v_{0}$ is the carrier frequency, $m$ is the modulation index, and $\omega$ is the modulation frequency.

FIG. 1. (color online) (a) Detection scheme of the improved three dimensional fluorescence modulation spectroscopy of the $0_{g}^{-}$state of $\mathrm{Cs}_{2}$ dissociating towards the $\left(6 S_{1 / 2}+6 P_{3 / 2}\right)$ limit. (b) Noise power spectra of cold atomic fluorescence versus modulation frequency. The inset shows the low frequency part.

The intensity of the coupling laser is set to be very weak ( $10 \%$ of the trapping laser power), which is the best power with little trapped cold atoms be heated to escape from MOT despite the maximum absorption. Note that the coupling laser frequency is the same as the trapping laser with a red detuning of $\sim 10 \mathrm{MHz}$ relative to the Cs atomic resonant frequency in our measurement. We apply the optimal values of modulation index and frequency, $m=2$ and $\omega=3.3 \mathrm{kHz}$. Fig. $1(\mathrm{~b})$ shows the noise power spectra of the cold atoms' fluorescence in MOT and the electronic noise of the detection system. The modulation signal and its high-order terms are
clearly demonstrated. The demodulated signal in the first-order (the purple curve in the inset of Fig. 1(b)) corresponds to a best signal-to-noise ratio (SNR) of 14.5. Therefore, we take first-order $\omega$ as the demodulation reference frequency.

FIG. 2. (color online) (a) Schematic of vibrational levels ( $v$ $=2, v=1$, and $v=0$ ) in potential curve of $0_{g}^{-}$external well are indicated by straight olive, purple, and blue, respectively. The vibrational spectroscopy of $v=2, v=1$, and $v=0$ are shown in (b), (c), and (d). The inset of (b), (c), and (d) show the rotational spectroscopy for $v=2, v=1$, and $v=$ 0 , respectively.

Fig. 2(a) describes the position of vibrational levels $(v=2, v=1$, and $v=0)$ in the $\mathrm{Cs}_{2} 0_{g}^{-}$external well by theory predictions [11]. In our experiment, the PA laser frequency was tuned to about $11654.6 \mathrm{~cm}^{-1}$ for observing the spectra of $v=2$ (olive line), which was recognized as the lowest vibrational level $v^{\prime}=0$ in the previous experiments $[6,9,10]$. The two deeper levels are two missing lowest levels $v=1$ and $v=0$ (purple and blue lines, shown in Fig. 2 (a)), which theoretically predicted by O. Dulieu, et al. are firstly been observed in our experiment. Well resolved PA spectra of the vibrational quantum number $v=2$ of the $0_{g}^{-}\left(6 P_{3 / 2}\right)$ PLR state of $\mathrm{Cs}_{2}$, whose detuning is red shifted for $\sim 77.5 \mathrm{~cm}^{-1}$ from the $6 S_{1 / 2}+6 P_{3 / 2}$ dissociation limit, is shown in Fig. 2(b). Rotationally resolved trap loss spectra for $v=2$ of $\mathrm{Cs}_{2} \mathrm{PLR}$ state up to $J=5$ is shown in the inset of Fig. 2(b). The difference ( $0.42 \mathrm{~cm}^{-1}$ ) of rotational level energies between our spectra and the experimental spectra of Ref. [16] stems from the difference in calibration benchmark of PA laser frequency. The line shape of the spectra for the different J is the same as reported in Ref. [17]. As shown in Fig. 2(c), the PA line intensity of the vibrational level $v=1$ of the $\mathrm{Cs}_{2} 0_{g}^{-} \mathrm{PLR}$ state is very small as expected to be, whose detuning is red shifted for $\sim 79.5 \mathrm{~cm}^{-1}$ from the $6 S_{1 / 2}+6 P_{3 / 2}$ dissociation limit. Fig. 2(d) demonstrates the observed PA spectra of the missing lowest vibrational level $v=0$ of the $\mathrm{Cs}_{2} 0_{g}^{-} \mathrm{PLR}$ state, whose detuning is red shifted for $\sim 81.6 \mathrm{~cm}^{-1}$ from the $6 S_{1 / 2}+6 P_{3 / 2}$ dissociation limit. The signal-to-noise
ratio of rotational spectra is too poor to distinguish rotational lines $J=0$ and $J=1$, shown in the inset of Fig. 2(d), because of the extremely tiny Franck-Condon factor. The experimental energies of the $v=2$ and missing levels of the $\mathrm{Cs}_{2}$ PLR state are shown in Table I. The uncertainty is mainly due to a possible systematic error in the process of fitting and error in the determination of the resonant line position.

For represent the potential energy curve with the missing lowest levels of the $\mathrm{Cs}_{2} 0_{g}^{-}$PLR state, we have used the analytical asymptotic approach [11]. In Hund's case-c representation, the $0_{g}^{-}\left(6 S_{1 / 2}+6 P_{3 / 2}\right)$ double-well state arises from the mixing between the ${ }^{3} \Pi_{g}(6 S+6 P)$ and ${ }^{3} \Sigma_{g}^{+}(6 S+6 P)$ Hund's case-a states. The $2 \times 2$ matrix of the Hamiltonian describing this mixing can be written as [11]:

$$
H=\left(\begin{array}{cc}
V^{\Pi}(R)-\Delta^{\Pi \Pi}(R) & \frac{\sqrt{2} M^{2} \epsilon}{9 R^{3}}+\Delta^{\Pi \Sigma}(R)  \tag{1}\\
\frac{\sqrt{2} M^{2} \epsilon}{9 R^{3}}+\Delta^{\Pi \Sigma}(R) & V^{\Sigma}(R)
\end{array}\right)
$$

where the $V^{\Pi}(R)$ and $V^{\Sigma}(R)$ are the ${ }^{3} \Pi_{g}$ and ${ }^{3} \Sigma_{g}^{+} \quad$ asymptotic potentials, $\Delta^{\Pi \Pi}(R)$ and $\Delta^{\Sigma \Pi}(R)$ are the $R$-dependent spin-orbit interaction within the ${ }^{3} \Pi_{g}$ manifold and between the ${ }^{3} \Pi_{g}$ and ${ }^{3} \Sigma_{g}^{+}$ states, respectively. The asymptotic potentials $V^{\Pi}(R)$ and $V^{\Sigma}(R)$ are given by

$$
\begin{align*}
& V^{\Sigma}(R)=-\frac{C_{3}^{\Sigma}}{R^{3}}\left(1+\frac{2 \epsilon}{3}\right)-\frac{C_{6}^{\Sigma}}{R^{6}}-\frac{C_{8}^{\Sigma}}{R^{8}}+V_{e x c h}^{\Sigma}  \tag{2}\\
& V^{\Pi}(R)=-\frac{C_{3}^{\Pi}}{R^{3}}\left(1+\frac{4 \epsilon}{3}\right)-\frac{C_{6}^{\Pi}}{R^{6}}-\frac{C_{8}^{\Pi}}{R^{8}}+V_{e x c h}^{\Pi} \tag{3}
\end{align*}
$$

The relativistic effects are introduced in these equations as a small correction to the coefficients of the $R^{-3}$ terms [11, 12], the parameter $\epsilon$ characterizing the ratio of the squared transition moments $M_{1 / 2}$ and $M_{3 / 2}$ corresponding to the relativistic $P_{1 / 2}$ and $P_{3 / 2}$ states

$$
\begin{equation*}
\Re=\frac{\left(M_{3 / 2}\right)^{2}}{\left(M_{1 / 2}\right)^{2}}=\frac{2 \tau_{1 / 2}\left(\lambda_{3 / 2}\right)^{3}}{\tau_{3 / 2}\left(\lambda_{1 / 2}\right)^{3}}=\frac{2}{(1+\epsilon)^{2}} \tag{4}
\end{equation*}
$$

where $\left(\lambda_{3 / 2}\right)^{-1}=11732.3071 \mathrm{~cm}^{-1}$ and $\left(\lambda_{1 / 2}\right)^{-1}=$ $11178.2682 \mathrm{~cm}^{-1}$ are the $6 p_{3 / 2.1 / 2} \rightarrow 6 s$ transition wave numbers [12]. The $M^{2}$ coefficient in Eq.(1) is related to the $\mathrm{C}_{3}^{\Sigma / \Pi}$ coefficients by

$$
\begin{equation*}
C_{3}^{\Pi}=-\frac{C_{3}^{\Sigma}}{2}=-\frac{M^{2}}{3} \tag{5}
\end{equation*}
$$

and it is related to the relativistic atomic transition moment corresponding to $j=3 / 2$ by

$$
\begin{equation*}
M^{2}=\frac{3}{4}\left(M_{3 / 2}\right)^{2} \tag{6}
\end{equation*}
$$

The $V_{\text {exch }}^{\Sigma / \Pi}$ is the exchange energy between the two atoms [18]. The spin-orbit interaction terms are given by

$$
\begin{gather*}
\Delta^{\Pi \Pi}(R)=\frac{\Delta E_{f s}}{3} \tanh \left(A^{\Pi \Pi} R\right) \\
\Delta^{\Pi \Sigma}(R)=\frac{\sqrt{2} \Delta E_{f s}}{3} \tanh \left(A^{\Pi \Sigma} R\right) \tag{8}
\end{gather*}
$$

where $\Delta E_{f s}=554.039 \mathrm{~cm}^{-1}$ is the Cs $6 p$ fine structure splitting [11, 12].

Diagonalization of the $2 \times 2$ matrix of Eq. (1) yields an analytical expression for the potential curve of the $\mathrm{Cs}_{2} 0_{g}^{-}$ external well. We used a minimization procedure based on the so-called generalized simulated annealing (GSA) method to minimize root-mean-squared (rms) deviation [19]. Nine parameters were at first considered, as in Ref. [11]: the squared atomic transition moment $M^{2}$, the relativistic parameter $\epsilon$, the multipole coefficients $C_{6}^{\Sigma}, C_{6}^{\Pi}$, $C_{8}^{\Sigma}, C_{8}^{\Pi}$, the values $A^{\Pi \Pi}$ and $A^{\Pi \Sigma}$ of the spin-orbit variation parameters, and the exchange amplitude $a_{6 s} a_{6 p}$.

TABLE II. Result of the present work, together with the result of Ref. [11] and with some theoretical values. The standard deviation of the parameters is indicated in parentheses.

| parameters | this paper | Ref. [11] | theory |
| :--- | :--- | :--- | :--- |
| $M^{2}\left(10^{5} \mathrm{~cm}^{-1} \AA^{3}\right)$ | $9.808(1)$ | 9.806 | $10.22[20]$ |
| $\mathrm{C}_{6}^{\mathrm{I}}\left(10^{7} \mathrm{~cm}^{-1} \AA^{6}\right)$ | $5.78(1)$ | 5.869 | $5.701[20]$ |

| $\mathrm{a}_{65} \mathrm{a}_{6 p}$ | $0.04150(4)$ | 0.04512 | $0.05479[18]$ |
| $\varepsilon 10^{-3}$ | $4.79 \quad(2)$ | 4.81 |  |

In order to obtain the best possible fit, we restricted the experimental data to the 76 lowest vibrational levels from $v=0$ to $v=75$ to the rotational level $J=2$, which corresponds to and by far the most intense lines of the observed rotational progression involving $J=0-6$. The experimental energy levels lying in the $\mathrm{Cs}_{2} 0_{g}^{-}$external well are produced with a rms of $0.0035 \mathrm{~cm}^{-1}$. The Table II presents the asymptotic parameters obtained from this analysis, together with the result of Ref. [11] and with some theoretical values $[18,20]$. We determine a standard deviations on the parameters by fitting 100 sets of experimental energies, obtained after adding a random distribution of the experimental error bar $\left( \pm 0.006 \mathrm{~cm}^{-1}\right)$ over the measured energies. The values obtained for the
parameters $A^{\Pi \Sigma}$ and $A^{\Pi \Pi}$ were rather large, so that the spin-orbit interaction was hardly varying in the $R$ range of the $0_{g}^{-}$external well. Thus, we therefore suppressed these two parameters by giving them fixed infinite values. The adjusted values for the $\epsilon, M_{2}, C_{3}$ and $C_{6}$ are not very different from the ones of Ref. [11] and are in good agreement with the theoretical predictions (with a relative difference smaller than $5 \%$ ). The value of the parameter $\epsilon=4.79 * 10^{-3}$ is slightly smaller compared to the values in Ref. [11]. The differences in the value of $C_{8}^{\Pi}$ is closer to the value in Ref. [11], a little bigger compared to the theoretical value of Ref. [20] (with a relative difference smaller than $9 \%$ ). The value of $C_{8}^{\Sigma}$ is a little smaller than the one in Ref. [11] but still more than twice as large as the theoretical values of Ref. [20]. The value obtained for the asymptotic exchange amplitude $a_{6 s} a_{6 p}$ is closer to the one in Ref. [11] and the theoretical value of Ref. [18]. The $\mathrm{Cs}_{2} 0_{g}^{-}\left(6 P_{3 / 2}\right)$ external well potential curve is represented with and without two missing lowest levels, respectively, as shown in Fig. 3. The potential minimum with two missing lowest levels (black full lines) is obtained at $\mathrm{R}_{\text {min }}=12.52(1) \AA$, which is slightly smaller than without two missing lowest levels (red dashed lines $\left.\mathrm{R}_{\min }=12.69(1) \AA\right)$ and with a minimum value $\mathrm{E}_{\text {min }}=$ $-81.864(3) \mathrm{cm}^{-1}$, which is notably deeper than the red dashed one $\left(\mathrm{E}_{\text {min }}=-78.004(5) \mathrm{cm}^{-1}\right)$.

FIG. 3. (color online) Potential curve of the PLR $0_{g}^{-}\left(6 P_{3 / 2}\right)$ external well of $\mathrm{Cs}_{2}$, obtained with the missing lowest levels $v=1$ and $v=0$ (black full lines) and without the missing lowest levels (red dashed lines). Insets (a) and (b) emphasize the differences between the two curves in the region at the large and minimum distance, respectively.

The most important result of present work is the determination of the lifetimes $\tau_{3 / 2}$ and $\tau_{1 / 2}$ of the $6 P_{3 / 2}$ and $6 P_{1 / 2}$ atomic levels, respectively [11]. The atomic lifetimes values can be deduced from the adjusted parameter $M^{2}$ by

$$
\begin{gather*}
\tau_{3 / 2}=\frac{9 \hbar}{4 M^{2}}\left(\frac{\lambda_{3 / 2}}{2 \pi}\right)^{3},  \tag{9}\\
\tau_{1 / 2}=\tau_{3 / 2}\left(\frac{\lambda_{1 / 2}}{\lambda_{3 / 2}}\right)^{3} \frac{1}{(1+\epsilon)^{2}} . \tag{10}
\end{gather*}
$$

where the $M^{2}$ and $\epsilon$ corresponding to the fit of Table $\mathrm{I}, \tau_{3 / 2}=30.44 \pm 0.06 \mathrm{~ns}$ and $\tau_{1 / 2}=34.81 \pm 0.07 \mathrm{~ns}$, in agreement with $\tau_{3 / 2}=30.41 \pm 0.30 \mathrm{~ns}$ and $\tau_{1 / 2}=$ $34.82 \pm 0.36 \mathrm{~ns}[11], \tau_{3 / 2}=30.41 \pm 0.10 \mathrm{~ns}$ and $\tau_{1 / 2}=$ $34.75 \pm 0.07 \mathrm{~ns}$ [21], and $\tau_{3 / 2}=30.39 \pm 0.06 \mathrm{~ns}$ and $\tau_{1 / 2}=34.80 \pm 0.07 \mathrm{~ns}$ [22]. The relative uncertainty on these value is the same as the one on $M^{2}$ of the order of $0.2 \%$. Moreover, we can use the method of Ref. [23] to deduce the $C_{6}$ coefficient by

$$
\begin{equation*}
C_{6}=M_{1 / 2}^{4} \xi_{P}+M_{1 / 2}^{2} \xi_{x}+\xi_{r} \tag{11}
\end{equation*}
$$

where $\xi_{P}, \xi_{x}$, and $\xi_{r}$ are coefficients evaluated by [23]. From our value of $\tau_{3 / 2}$ and $\Re$, we can derive $M_{1 / 2}$ and finally obtain $C_{6}=6852 \pm 25$ a.u., in good agreement with the values $6850 \pm 140$ a.u. [11], $6860 \pm 25$ a.u. [24] and $6846 \pm 16$ a.u. [25]. The uncertainty of $0.36 \%$ in $C_{6}$ is estimated by considering the uncertainties on the $\xi_{P}, \xi_{x}$, and $\xi_{r}$ parameters reported in Ref. [24], and the one on $\Re$ from our analysis.

In conclusion, we report the observation of the predicted levels of PLR $\mathrm{Cs}_{2}$ by PA spectroscopy, which are theoretically predicted by Olivier Dulieu, et al. [11]. The vibration quantum numbers of $\mathrm{Cs}_{2} 0_{g}^{-}$state are modified as $\mathrm{v}=\mathrm{v}^{\prime}+2$.
