Coherent narrow band extreme ultraviolet (EUV) light is generated by a near-resonant four wave mixing (FWM) process between attosecond pulse trains and near infrared pulses in neon gas. The near-resonant FWM process involves one vacuum ultraviolet photon and two near-infrared (NIR) photons and produces new higher energy frequency components corresponding to the *ns/nd* to ground state  $(2s^22p^6)$  transitions in the neon atom. The EUV emission exhibits small angular divergence (2 mrad) and monotonically increasing intensity over a pressure range of 0.5-16 Torr, suggesting phase matching in the production of the narrow bandwidth coherent EUV light. In addition, time-resolved scans of the NIR nonlinear mixing process reveal the detection of a persistent, ultrafast bound electronic wavepacket based on a coherent superposition initiated by the vacuum ultraviolet (VUV) pulse in the neon atoms. This FWM process using attosecond pulses offers a means for both efficient narrowband EUV source generation and time-resolved investigations of ultrafast dynamics.

#### I. Introduction

When matter is exposed to a strong optical electric field, electrons are over-driven to produce a polarizability that is not linear with the intensity of the incident electric field. This nonlinear response is the essence of all non-linear spectroscopies[1-2]. It is the basis for developing new frequency light sources through nonlinear optical methods including frequency doubling and tripling, four wave mixing (FWM), and high order harmonic generation [3-10]. The nonlinear response also underlies time-resolved studies of ultrafast dynamics in atoms [11], molecules [12-14] and solids [15-16]. Ultrafast nonlinear spectroscopy such as coherent Raman scattering, time-resolved FWM, and multi-dimensional spectroscopy relies on intense coherent light sources, and has developed dramatically in the optical and infrared regimes owing to advances in laser development. The extension of these applications towards the extreme ultraviolet (EUV) or even x-ray regime has potential to uncover rich structural and dynamical information with even higher time resolution [17]. However, the technical difficulties with generating EUV/x-ray light sources that achieve both high intensity and temporal coherence hinders such direct applications. Recently, experimental evidence for a time-resolved FWM signal in the EUV regime has been reported using a few tens of femtosecond FEL pulses, revealing the dynamics of collective vibrational modes in SiO<sub>2</sub> [16]. However, tracking faster dynamics such as electronic motions requires shorter EUV pulses with few femtosecond or even subfemtosecond duration. High order harmonics (HH) have

two key characteristics: a broad spectral range spanning from the VUV to the soft x-ray and regular spectral phase that supports extremely short light burst generation [18-19]. Therefore HH serve as an excellent FWM mixing source with both wide wavelength tunability and unprecedented time resolution for triggering ultrafast dynamics.

In this work, we report experimental evidence for FWM in the EUV using a HH based attosecond pulse train (APT). The APT alone cannot induce a nonlinear response in a medium due to its low photon flux. In order to ease the intensity requirement, a strong NIR pulse provides the intensity necessary to achieve an appreciable third order nonlinear effect. We utilize an APT consisting of three harmonics (11th, 13th [suppressed] and 15th) with an intensity ratio of 40:1:6 to achieve FWM in neon gas medium. Such a HH pulse contains predominantly a single harmonic (11th harmonic) below the ionization threshold of neon atom, thus effectively inducing a clean FWM signal that dominates over the background signal at the energy of the 13th harmonic. Figure 1 shows the energy diagram for the FWM process. Ne atoms are resonantly excited to the 3s manifold by the APT by absorbing a single photon  $\omega_1$  (near 17 eV). The NIR pulse then couples the 3s states to the ns/nd manifold near 20 eV by two NIR photons. Since a dark state (3p) near resonance with the 3s states exists, the two IR photons can be absorbed resonantly, which greatly enhances the third order nonlinear susceptibility  $\chi^{(3)}$ . The coherence between the ns/nd states and the ground state forms an oscillating dipole, which emits a photon  $\omega_4$  to complete the nonlinear process. As a result of the nonlinear interaction, narrowband new frequencies in EUV region

with low divergence are observed. The photon flux at these new frequencies grows monotonically with the gas pressure, demonstrating phase-matching [10, 20]. In addition, the intensities of the newly generated frequency components show a sensitive dynamical dependence on the relative delay between the HH and NIR pulses, in which the information for an electronic wave packet (coherent superposition) is encoded.

#### II. Experimental method

The experimental setup is similar to an attosecond transient absorption (ATA) configuration [21] as shown in Figure1.

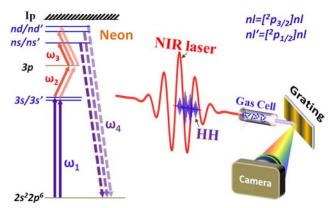

Fig 1. Energy diagram of the FWM driven by a weak APT and a moderately intense NIR laser.

HH are generated from Xenon gas using a 6 femtosecond 300 µJ few-cycle NIR pulse with a spectrum spanning from 550 nm to 950 nm. The generated HH pass through a 100 nm indium filter to block the residual NIR field from the HH generating field; an added benefit of the indium filter is dramatic suppression of the 13<sup>th</sup> harmonic. The harmonics consisting of the dominant 11<sup>th</sup> and 15<sup>th</sup> harmonics form an APT with a period of  $T_0/4$ , which is determined by the energy separation of the two dominant harmonics [18-19].  $T_0$  is the cycle of the NIR laser. A replica of the few-cycle NIR pulse is picked off from the original pulse and combined spatiotemporally with the APT with an annular mirror. Both the HH and NIR pulses propagate collinearly and are focused into the 1 mm FWM gas cell filled with neon atoms at 0.5 - 16 Torr. The intensity of the NIR pulse inside the neon gas cell is approximately  $2 \times 10^{12}$  W/cm<sup>2</sup> throughout except the intensity dependent measurement as shown in Figure 3(b). The NIR field after the neon FWM gas cell is blocked by a 200 nm aluminum filter. The optical spectrum in the EUV region after the gas cell is recorded by an EUV spectrometer consisting of a flat field grating and a CCD camera.

#### III. Results and discussion

#### A. Coherent EUV light generation

The EUV spectrum with and without the neon medium present is shown in Figure 2. The original HH spectrum consists of three harmonics with the 13<sup>th</sup> harmonic strongly suppressed by the indium filter as noted above (see inset in Figure 2). The peak intensity ratio of the three harmonics, after correcting for the aluminum filter transmission curve and the CCD camera quantum efficiency, is 40:1:6. Thus the original HH spectrum below the ionization threshold (21.56 eV) of neon is dominated by the 11<sup>th</sup> harmonic (16.5 eV), which is essential to launch a clean FWM process. When the NIR pulse is switched on during and after the HH attosecond pulses. narrow bandwidth frequency components with low divergence (see the inset of Figure 2) in the vicinity of the neon atomic transitions are generated. The widths of the individual emission peaks are limited by the spectrometer resolution (35 meV at 20 eV). These newly generated coherent emissions have a photon energy roughly 3.5 eV above the dominant 11th harmonic (~16.5 eV), indicating a nonlinear process. A near resonant FWM process involving a VUV photon (16.8 eV) and two NIR photons (~1.6 eV) is responsible for the narrowband EUV light generation based on energy conservation.

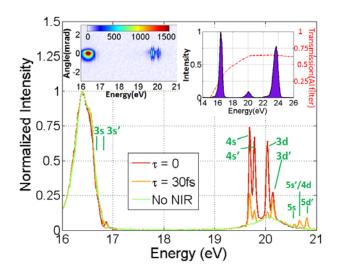

Fig.2. EUV spectra after the nonlinear medium. The gas pressure is 2.85 Torr. New frequencies are generated when the NIR pulse arrives during (red) and after (orange) the HH pulses. The left inset shows the two dimensional spectrum on the CCD camera. The right inset is the integrated spectrum without gas medium. Red dashed line is the transmission curve of the aluminum filter. Spectra are normalized to the peak of the 11<sup>th</sup> harmonic.

The yield of the newly generated EUV components via FWM as a function of gas pressure is shown in Figure 3(a). The gas pressure is estimated based on the absorption of the  $15^{\text{th}}$  harmonic using the literature absorption cross-section

of neon above the ionization threshold [22]. The experiment demonstrates a monotonic growth of the EUV emission yield with gas pressure up to 16 Torr (2133 Pa), indicating that phase-matching is occurring for efficient EUV source generation. The FWM efficiency can be estimated by dividing the integrated photon flux of the emission features by that of the 11<sup>th</sup> harmonic; it is approximately 22% at zero delay with a pressure of 16 Torr and quickly drops to a few percent at delays beyond the overlap region. The higher efficiency at zero delay implies an important contribution from non-resonant processes.

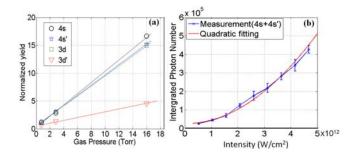

Fig.3. (a) Integrated intensity of different emission peaks versus the gas pressure. The yield is normalized to the peak of the 11<sup>th</sup> harmonic. (b) Integrated intensity of the 4s/4s' emission features as a function of the NIR intensity. The HH-NIR delay is zero.

The intensity of the emitted feature around 20 eV is determined by two factors: the third order susceptibility of the corresponding FWM process  $\chi^{(3)}$ , which describes the nonlinear efficiency per atom, and the phase-mismatch between the driving sources and the emitted light:  $\Delta k = k_{11th}+k_{ir1}+k_{ir2}-k_{euv}$ , which quantifies the coherent build-up of the photon flux through the medium.  $k_{11th}, k_{ir1}, k_{ir2}$  and  $k_{euv}$  represent the wave-vectors of the 11<sup>th</sup> harmonic photon, two NIR photons and the generated EUV photon, respectively. In the experiment, a loose focusing geometry is used, and the confocal length of both the HH and IR beams is much longer than the length of the gas cell. Therefore the NIR Gouy phase [23] induced phase mismatch is neglected. The wave vector  $k(\omega)$  is related to the linear susceptibility  $\chi^{(1)}(\omega)$ 

as: 
$$k(\omega) \propto \omega \Re\left[\sqrt{1 + \chi^{(1)}(\omega)}\right], \chi^{(1)}(\omega) \propto \sum_{f} \frac{\omega_{gf} \mu_{gf}^{2}}{\omega_{gf}^{2} - \omega^{2}}. \Re$$
 denotes

the real part,  $\omega_{gf}$  is the energy difference between the ground state  $|g\rangle$  and an excited state  $|f\rangle$ , and  $\mu_{gf}$  is the corresponding dipole matrix element. A Taylor expansion of the wave-vector to first order gives:  $k(\omega) \propto \omega \left[1 + \frac{1}{2} \Re \left[\chi^{(1)}(\omega)\right] + ...\right]$ , and the phase mismatch

reduces to:

$$\Delta \mathbf{k} \propto \Re \Big[ \omega_{11th} \chi^{(1)}(\omega_{11th}) + \omega_{r1} \chi^{(1)}(\omega_{r1}) + \omega_{r2} \chi^{(1)}(\omega_{r2}) - \omega_{euv} \chi^{(1)}(\omega_{euv}) \Big]$$
(1)

The contribution from the far-off-resonance NIR beam to phase-mismatch is negligible,  $\Delta k$  is therefore dominated by

the two resonant beams  $\omega_{11th}$  and  $\omega_{euv}$  [3,9]:

$$\mathbf{k} \propto \sum_{f} \omega_{gf} \, \mu_{gf}^{2} \left( \frac{\omega_{11th}}{\omega_{gf}^{2} - \omega_{11th}^{2}} - \frac{\omega_{euv}}{\omega_{gf}^{2} - \omega_{euv}^{2}} \right) \ (2)$$

Due to the un-matched frequencies and dipole matrix elements in the two resonant terms of equation (2), both transitions need to be red(blue) detuned from the resonance to satisfy the phase matching, therefore greatly reducing the re-absorption of the generated EUV signal. Under the phase matching condition, the different slopes in Figure 3(a) indicates different nonlinear susceptibilities  $\chi^{(3)}$ , for different final states. The maximal gas pressure is limited by the vacuum environment required by the CCD camera, we expect a brighter EUV source to be generated by increasing the cell length or pressure if the experimental conditions allow.

#### B. Time-resolved Four Wave Mixing

The above discussion demonstrates nonlinear generation of narrowband EUV light using a weak HH field as the mixing source. The HH field is localized in a series of attosecond bursts in the time domain. This allows a time-resolved FWM study to explore the dynamics of a coherent superposition of electronic states initiated by the HH pulses. Figure 4(a) shows the EUV spectra after the neon gas medium as a function of HH-NIR time delay. The onset of narrowband EUV emissions occurs when the NIR pulse arrives during or immediately after the HH pulse. However, the intensity of each individual emission feature oscillates out to longer times versus time delay. A Fourier analysis of the oscillations (Figure. 4(b)) shows that all the emission features share a common oscillation period of about 25 fs (angular frequency is 0.16 eV/ $\hbar$ ). In addition, the emission features in the vicinity of the [<sup>2</sup>P<sub>3/2</sub>]4s/[<sup>2</sup>P<sub>1/2</sub>]4s to ground state  $(2s^22p^6)$  transitions (~19.75 eV) show a relatively weaker sub-cycle modulation with a period close to 1.3 fs (angular frequency is  $3 \text{ eV}/\hbar$ ).

To understand the various timescales in Figure 4, we write the polarization induced by the HH and NIR pulse at frequency  $\omega$  as a power series:

$$p(\omega) = \varepsilon_0 \chi^{(1)} \mathsf{E}_{\mathsf{HH}}(\omega) + \varepsilon_0 \chi^{(2)} \mathsf{E}_{\mathsf{HH}} \mathsf{E}_{\mathsf{NIR}} + \varepsilon_0 \chi^{(3)} \mathsf{E}_{\mathsf{HH}} \mathsf{E}_{\mathsf{NIR}} \mathsf{E}_{\mathsf{NIR}}$$
(3)

This perturbative treatment is validated by the observed quadratic increase of the FWM yield with the NIR intensity as shown in Figure 3(b). The first term in equation (3) is the linear response of neon gas to the HH field. The second term typically vanishes due to the inversion symmetry of the atomic system. The third term represents the nonlinear FWM process discussed in this work. For a broadband HH driving source that can provide frequencies to drive both the first (one photon pathway) and the third term (three photon pathway), modulations in the intensity of absorptions lines are expected due to the interference of the two pathways. This is the characteristic for a typical ATA experiment, and the "which-way" interference is the main mechanism of various oscillation features. As a result, the oscillation frequencies of different absorption lines lie on a line oriented at 45 degrees [24-29]. We therefore attribute the very fast oscillations with frequencies around  $3 \text{ eV}/\hbar$  (period

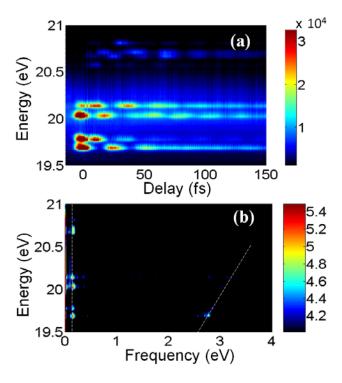

Fig.4. (a) EUV spectrum as a function of HH-NIR delay, HH attosecond pulses precedes the NIR for positive delays. (b) Fourier analysis (logarithm) of the spectrogram in (a) with respect to the delay axis. The gas pressure is 2.85 Torr.

of 1.3 fs) lying on a 45 degree line in Figure 4(b) to the one-photon versus three-photon pathway interference. In this experiment, the 13<sup>th</sup> harmonic that drives the first order process is strongly suppressed, and the spectrum near 20 eV is predominantly contributed by the third order nonlinearity, resulting in a rather weak sub-cycle oscillation related to the "which-way" interference.

Two spin-orbit split states,  $[{}^{2}P_{3/2}]3s$  and  $[{}^{2}P_{1/2}]3s$ , are simultaneously populated by the 11<sup>th</sup> harmonic, and two three-photon pathways can reach the same final state around 20 eV and also interfere; this is the dominant interference mechanism in the current FWM experiment. A time-resolved study can directly map out the beating frequency between the two states that are formed in a coherent superposition by the HH driving pulse. Therefore, we attribute the slow frequency components lying on a vertical line in Figure 4(b) to quantum beating between the  $[{}^{2}P_{3/2}]3s$  and  $[{}^{2}P_{1/2}]3s$  electronic states (splitting approximately 0.17 eV). Note that the oscillations of the EUV emission features show different phases. This indicates the competition between different FWM channels that share the transferred population from the same initial 3s/3s' states.

The results presented here differ from a recent study of neon using ATA spectroscopy that reported wavepacket dynamics imprinted on the absorption spectrum at similar photon energies [27]. That work revealed a longer modulation period (45 fs), corresponding to the energy spacing between two NIR coupled bright states ( $[^{2}P_{1/2}]_{3d}$ and  $[^{2}P_{3/2}]_{3d}$ ) and arising from interference between the 1<sup>st</sup> and 3<sup>rd</sup> order terms in Equation (3). Previous studies using photoelectron spectroscopy successfully observed both quantum beats and "which way" interference of helium atoms with scattering states as the final states [30]. Here we demonstrate an all-optical method of FWM with a bound state as the final state for detecting both ultrafast dynamic information of a bound electronic wavepacket.

In the measurement shown in Figure 4, the emission intensity decays quickly as the delay increases. The line-out at the energy corresponding to the 4s emission feature versus delay is shown in Figure 5(a) for different gas pressures. As the pressure increases, the decay becomes more severe and the quantum beat information is gradually lost. This indicates that the macroscopic propagation effect is playing a significant role in the resulting spectrogram. The temporal structure of the HH pulse train at the beginning of the gas medium is a regular APT with a duration of a few femtoseconds. Thus the excitation is prompt and serves as a precise timing tool to start the nonlinear process. As the HH pulse propagates through the resonant medium, its temporal structure will be elongated and distorted due to the interplay between the induced polarization and the original pulse [31-33]. Consequently, the initial excitation by the HH pulse is no longer prompt but persists for a longer time, thereby losing the ability to precisely clock the nonlinear process.

To get a better glimpse of the physical picture, we use a two-level model coupled with the 1D Maxwell's equation to simulate the interaction of an APT with a neon gas medium; only the ground state and one of the excited states  $([^{2}P_{3/2}]]$ 3s or  $[{}^{2}P_{1/2}]3s$ ) are considered. The calculated results are shown in Figure 5 (b). The population amplitude of the excited state decays quickly as the medium pressure is increased. Thus the effective nonlinear susceptibility  $\chi^{(3)}$  is reduced by the loss of coherence as the NIR pulse is introduced at later times, explaining the decay observed in the experiment. Since the dipole matrix elements related to the  $[{}^{2}P_{3/2}]$ 3s and  $[{}^{2}P_{1/2}]$ 3s differ by a factor of 3, as the propagation effects become important their excitation amplitudes show rather different time structures as shown in Figure 5(b). This difference is imprinted on the measurement shown in Figure 5(a) and blurs the quantum beating signal between the  $[{}^{2}P_{3/2}]3s$  and  $[{}^{2}P_{1/2}]3s$  states. The experimentally observed faster decay around zero delay is related to the non-resonant contribution that is ignored in the model calculation [34,35]. Although the bright EUV emissions in the vicinity of the transitions prefer higher gas pressure due to preserved phase-matching, the retrieval of accurate dynamical information requires a lower gas pressure where the distortion of the resonant excitation pulse is not too severe to degrade its timing ability. This differentiates the two conditions needed for the two applications of the current experimental method.

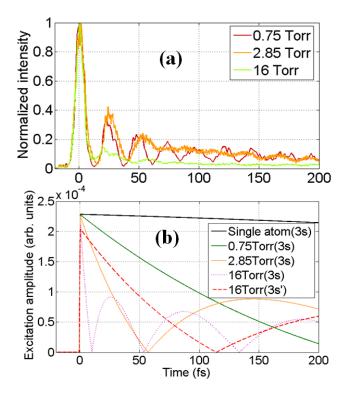

Fig.5. (a) Measured delay-dependent yield of the 4s emission feature under different gas pressures. (b) Calculated excitation amplitudes of 3s/3s' states by the HH pulse, interaction length is 1mm. Dipole matrix elements are adapted from reference [22].

#### IV. Conclusion

In conclusion, we experimentally demonstrated the nonlinear response of neon gas to an APT synchronized with a NIR laser pulse. New frequency components in the EUV region, featuring narrow bandwidth and low divergence, are generated by a near-resonant four-wave mixing process. The efficiency of the nonlinear emission intensity grows monotonically with the gas pressure, revealing the phase-matching nature. A time-resolved study of this nonlinear interaction successfully recovers the recurrence of bound state electronic wavepacket motion initiated by the attosecond pulses by FWM detection in the EUV. This homodyne detection method not only provides an efficient route for coherent EUV source generation, but also offers a background free nonlinear EUV signal for accessing clean dynamics following electronic excitation, which is generally challenging in ATA spectroscopy due to the complex mixture of multiple physical processes. This all-optical methodology holds promise to be extended to more complex systems such as molecules for applications including tunable bright coherent light generation and time resolved ultrafast dynamics driven by electronic-nuclear coupling.
