(Dated: November 11, 2016)

Experiments in the field of optomechanics do not yet fully exploit the photon polarization degree of freedom. Here experimental results for an optomechanical interaction in a polarization non-degenerate system are presented and schemes are proposed for how to use this interaction to perform accurate side-band thermometry and to create novel forms of photon-phonon entanglement. The experimental system utilizes the compressive force in the mirror attached to a mechanical resonator to create a micro-mirror with two radii of curvature which leads, when combined with a second mirror, to a significant polarization splitting of the cavity modes.

Coupling mechanical motion to electromagnetic radiation lies at the heart of cavity optomechanics. Because the coupling is so general, a wide variety of experiments exist. For example the scale on which the mechanical motion takes place can range from suspended macroscopic mirrors [1–3] to cold atoms coupled to an optical cavity [4], see [5] for a review. Also the source of electromagnetic radiation varies greatly, ranging from the microwave [6, 7] to the optical domain [8–11]. Each device and set-up has its own advantages. In the optical domain, the availability of the polarization degree of freedom adds an additional knob for controlling and tuning the optomechanical devices. This means that techniques and methods from several landmark experiments demonstrating photon-photon [12, 13] or photon-matter [14, 15] entanglement can be implemented in existing optomechanical set-ups. However, so far, polarization has mostly been used to experimentally separate different optical signals and is not yet considered as a degree of freedom in, e.g., proposals [16–20] and experiments [21, 22] on photon-phonon entanglement.

This is understandable since the mechanical mode in an optomechanical system is not sensitive to the polarization of the incoming photon. However, the optical mode can be engineered to be polarization sensitive. Birefringence or astigmatism can cause a polarization splitting of the (fundamental) mode of an optical cavity. Although such birefringence has been observed before in optomechanical set-ups, it has been regarded as a parasitic effect [23, 24]. In this article we show an optomechanical system in which a significant polarization splitting of the fundamental mode is present. After a brief characterization of the set-up we show how for a single laser frequency, the interaction can be changed from cooling to driving simply by varying the polarization. Finally some advantages of a polarization non-degenerate optomechanical system are discussed.

In a Fabry-Perot based system birefringence occurs when one cavity mirror, either the stationary or the movable mirror, has two radii of curvature. We chose to use

Figure 1. (a) Compressive stress in the DBR layers causes the mirror to buckle. (c) Local radius of curvature as function of angle obtained for the off center location indicated with the white dot in (b). (d) Demonstration of mode splitting for an off axis aligned cavity by monitoring the transmitted intensity when the laser frequency is varied.

the curvature already present in the mirror attached to a trampoline resonator. The trampoline resonator consists of multiple DBR layers on top of a patterned silicon nitride membrane (see inset Fig. 1a). Finite element analysis using COMSOL shows that the compressive force in the DBR mirror is much larger than the tensile force in the silicon nitride causing the mirror to buckle slightly. This is schematically depicted in Fig. 1a. We have confirmed the mirror curvature with an optical profiler. Fig. 1b shows a concave mirror surface. Such small high quality curved mirrors are already interesting on their own to make small micro cavities for cavity QED experiments. For a polarization non-degenerate cavity however, an astigmatic mirror is needed.

\* buters@physics.leidenuniv.nl

Closer inspection of the mirror surface reveals a four-fold symmetry for the curvature in the center of the mirror, as expected from the geometry of the trampoline resonator. Because the DBR mirror is over-sized, 110  $\mu\text{m}$  diameter, compared to the beam size, typically 12  $\mu\text{m}$  diameter, a high quality cavity can still be constructed by placing the beam off-axis. It is therefore interesting to look at the local curvature away from the middle. For the white dot in 1b we determine the local radius of curvature (ROC) by fitting a parabola to a line-cut straight through the center of the white dot (see dashed line 1b). From the derivative of the parabola the ROC is obtained [25]. If we repeat this procedure for linecuts at different angles we obtain Fig. 1c. A clear two-fold symmetry is present, with a minimum ROC of about 1 mm and a maximum ROC of about 4 mm. Using these numbers together with the recently published work by Uphoff et al. [26], a polarization splitting of about 60 kHz for the fundamental mode is expected, based on the parameters of the set up.

To demonstrate such a splitting, a 5 cm long Fabry-Perot cavity operating around 1064 nm is placed in a vibration isolated vacuum chamber. In this configuration the convex side of the trampoline resonator faces the stationary mirror. The fundamental mode of the cavity is aligned such that the cavity mode is located on the side of the small curved mirror. The optical quality factor is constant with respect to beam placement, only near the very edge of the mirror does the optical quality degrade due to clipping of the beam. Both beam placement and optical quality factor are actively monitored during alignment to prevent this clipping of the beam. Via a cavity ringdown [27] the optical linewidth is determined to be  $51 \pm 1$  kHz and the mechanical resonator is characterized by measuring its mechanical thermal noise spectrum with a laser locked to a cavity resonance using the Pound-Drever-Hall (PDH) technique [28]. With this technique an intrinsic mechanical linewidth  $\Gamma_m$  of 19 Hz and a mechanical frequency  $\Omega_m$  of 222 kHz is measured.

To see if any polarization splitting is present, a laser is scanned across the cavity resonance and the input polarization is adjusted to address both polarization modes equally. A polarization splitting of  $83 \pm 1.0$  kHz is observed, as shown in Fig. 1d. This is of the same order as the expected polarization splitting of 60 kHz. Furthermore, the splitting is large enough to already show some interesting optomechanical effects. For this the measurement scheme outlined in ref. [27] is used. A probe laser at the cavity resonance is used to monitor the mechanical motion while the detuning of a second pump laser is varied.

For each specific laser detuning we measure the mechanical noise spectrum, fit a Lorentzian and extract the mechanical linewidth and frequency. The results are shown in Fig. 2. Note that the laser detuning is indicated for one of the two optical modes. The detuning for the other mode is shifted by 83 kHz, the polarization splitting. Since our optomechanical system operates in

Figure 2. (color online) Optomechanical interaction for a polarization non-degenerate cavity. Blue points are extracted from the Lorentzian fit to the mechanical resonance. Red is a simultaneous fit of the data with four free parameters: optical linewidth, optical splitting and input laser power for both modes. Green shows the contribution of the individual modes. (a) Mechanical frequency shift (b) Effective mechanical damping.

the linearized regime, the frequency shift and effective damping can be understood by adding the contributions of both modes:

$$\delta\Omega_{m,total} = \delta\Omega_{m,1} + \delta\Omega_{m,2} \quad (1)$$

$$\Gamma_{eff,total} = \Gamma_{opt,1} + \Gamma_{opt,2} + \Gamma_m \quad (2)$$

where  $\delta\Omega_{m,i}$  and  $\Gamma_{opt,i}$  are the optically induced frequency shift and damping (see for example ref. [5] for detailed expressions). In green the individual contribution from each mode is shown and in red the result of a fit for the combined effect of both modes. Note that the red curve in Fig. 2 and Fig. 3 is obtained from a single simultaneous fit to all data with only four free parameters: the optical linewidth, the mode splitting and the input power of both the horizontal and vertical polarization mode. From Fig. 2 we see that the experimental results are nicely described by the addition of the two separate contributions. Furthermore we obtain an optical linewidth  $\kappa$  of  $52 \pm 0.9$  kHz, a mode splitting of  $82.4 \pm 1.2$  kHz and an input laser power of  $2.19 \pm 0.04$   $\mu\text{W}$  and  $1.85 \pm 0.04$   $\mu\text{W}$  for both optical modes. These results are in good agreement with the optical characterization. It is also clear that at  $\Delta = 41.5$  kHz, precisely in between both optical modes, their contributions cancel.

This is even more clear when looking at the effective temperature of the mechanical mode, which is obtained from the area of the Lorentzian fit to the mechanical resonance. The theory curve for Fig. 3 is given by

$$T_{eff} = \frac{\hbar\Omega_m}{k_B} \frac{\bar{n}_{th}\Gamma_m + \bar{n}_{min}\Gamma_{opt}}{\Gamma_m + \Gamma_{opt}} \quad (3)$$

with  $\bar{n}_{min} = (\kappa/4\Omega_m)^2$  the theoretical minimum phonon number in the side-band resolved regime and  $\bar{n}_{th}$  the thermal phonon occupation number. For the optical damping  $\Gamma_{opt}$  we use the sum of the contributions from both modes (see Eq. 2). From the resulting graph of Fig. 3 we see again that the experimental results follow the

Figure 3. (color online) Effective temperature as a function of laser detuning. The arrow indicates the point where the contribution from both modes precisely cancel each other, leading to an effective temperature equal to the bath temperature.

theory nicely. Furthermore, at laser detuning  $\Delta = 41.5$  kHz indicated by the arrow, the effective mode temperature is just the environmental temperature, showing once more that the contribution from both polarization modes cancel out. However, if the laser is kept at  $\Delta = 41.5$  kHz and the input polarization is changed, one mode will dominate leading to either heating or cooling.

Of course the same effect can be obtained by using two lasers placed at either side of the cavity resonance, or perhaps even using higher order optical modes, but using the polarization degree of freedom as described above has several advantages. Because only a single frequency is used, the whole set-up has one common path, which improves the stability of the experiment. Secondly one single narrow linewidth laser frequency is needed. Furthermore only the fundamental Gaussian transverse mode is required, which has the same optical quality for both polarization modes. Finally the power ratio between the two modes is easily adjusted simply by rotating the incident polarization.

In principle these advantages are only technical. There are however interesting opportunities when the polarization splitting is precisely two times the mechanical frequency. For example an alternative method for side-band thermometry [29–33], which is the optomechanical equivalent to Raman-ratio thermometry in cold atoms [34] and solids [35], is possible. In Fig. 4 a laser,  $45^\circ$  linearly polarized, is placed precisely in the middle of the two polarization modes. Interaction with the horizontal mode leads to Stokes scattering, while interaction with the vertical mode leads to anti-Stokes scattering. For a large average phonon number  $\langle n \rangle$  both the horizontal mode (Stokes sideband) and vertical mode (anti-Stokes sideband) will exit the cavity with equal intensity. However, when the phonon occupation number is lowered, Stokes scattering becomes dominant and the light exiting the cavity will be mainly in the horizontal mode. Therefore the phonon number can be accurately obtained by measuring the ratio of transmitted light in the horizontal and vertical mode, since this will scale as  $1 + 1/\langle n \rangle$ .

Another interesting opportunity arises when a polar-

Figure 4. A polarization non-degenerate cavity with a splitting  $\delta = 2\Omega_m$ . H and V denote the different polarization and corresponding cavity mode.

ization non-degenerate system is prepared in the quantum mechanical ground state, a prerequisite for photon-phonon entanglement. Often a beamsplitter is used to create photon-photon entanglement [16–20]. For a polarization sensitive cavity this is no longer needed. If we again consider the situation of Fig. 4, but replace the laser with a single photon source, we see that entanglement arises when the incoming photon,  $45^\circ$  linearly polarized, is projected onto either basis state. By projecting onto the horizontal basis state, a phonon will be added to the mechanical resonator, while projecting onto the vertical basis state will extract a phonon. When, for example, starting from the  $\langle n \rangle = 1$  state, the mechanical resonator is put into a superposition between the ground state and the second excited state. This is not possible when a beamsplitter is used together with multiple laser frequencies. The addition of the polarization degree of freedom has created a new possibility to manipulate the state of the mechanical resonator. Furthermore, additional tools from the polarization-quantum optics toolbox can now be used. The input photon can be replaced with polarization entangled photon pairs, where one photon interacts with the resonator while the state of the other photon is monitored. We must however remark that for such single photon experiments either single photon strong coupling is required or a post selection method has to be implemented [36].

To access this new and interesting regime, a system with a polarization splitting of two times the mechanical frequency is needed. This requires only a small modification to the system presented here. Fabry-Perot based optomechanical systems are available with an optical linewidth smaller than 17 kHz, a mechanical frequency of 250 kHz and a mechanical quality factor approaching  $5 \times 10^5$  [37]. Taking this as a starting point, a cavity with a mode splitting of 500 kHz is needed. With some small modifications to the trampoline resonator design the mode splitting can be pushed from 83 kHz to about 100 kHz. Since the mode splitting scales inversely with cavity length [26], reducing the cavity length by a factor of five results in the desired mode-splitting. This

will also increase the optomechanical coupling strength  $g_0$  to about  $2\pi \times 8$  rad/s. A downside to this method is that the cavity linewidth increases by a factor of five, but an optical linewidth of 85 kHz is still sufficient to be side-band resolved. More importantly, to achieve groundstate cooling, the multi-photon cooperativity should be much larger than the thermal occupation number. In this case a base temperature of 1 K together with a laser power of 50  $\mu$ W is needed, which is experimentally feasible.

In conclusion, we have shown how a polarization non-degenerate optomechanical system can be a valuable addition to the existing optomechanical toolbox. We have created a system where optomechanical interaction with a single frequency laser can be tuned from cooling to heating simply by varying the incident polarization. On its own this offers some technical advantages, but combined with an optomechanical system close to the quantum ground state, this leads to new possibilities for photon - phonon entanglement. We have demonstrated how

such a system can be fabricated and showed that the last remaining step is to decrease the length to bring the presented system into the target regime.

## FUNDING INFORMATION

This work is part of the research program of the Foundation for Fundamental Research (FOM) and of the NWO VICI research program, which are both part of the Netherlands Organization for Scientific Research (NWO). This work is also supported by the National Science Foundation Grant No. PHY-1212483.
