In this paper we propose a scheme to model the phonon analog of optical elements, including a polarizing beam splitter, a half-wave plate, and a quarter-wave plate, as well as an implementation of CNOT and Pauli gates, by using two atoms confined in a 2D plane. The internal states of the atoms are taken to be Rydberg circular states. Using this model we can manipulate the motional state of the atom, with possible applications in optomechanical integrated circuits for quantum information processing and quantum simulation. Towards this aim, we consider two trapped atoms and let only one of them interact simultaneously with two circularly polarized Laguerre–Gaussian beams.

I. INTRODUCTION

Phonons can play a similar role to photons in quantum optics and quantum information processing. They can be used to encode information as qubits because of their appealing properties such as low-propagation speed, which provides us with new schemes for processing quantum information, and their short wavelength, which allows us to access regimes of atomic physics that cannot be reached in photonic systems [1]. Numerous researchers are trying to find ways of using phonons for quantum information and computation and, more importantly, finding ways for manipulating the quantum information that is carried by these phonons [2, 3, 4, 5, 6, 7].

Cold and trapped atoms are good candidates that provide the possibility of using of phonons (vibrational motion of the trapped atoms) in quantum information and quantum optics. This system has attracted more attention because of their appealing properties such as long lifetimes (single atoms can remain trapped for hours or days), long coherence times (ranging from milliseconds to seconds), natural reproducibility [8], high controllability and large nonlinearity, which originate from quantization of the motion [9]. Moreover, integrated quantum atom chips have become the focus of current research in atomtronics, which promises the miniaturization (and therefore scaling) of optical quantum circuits [10]. One important thing is to show how we can manipulate motional states of the atoms, especially on quantum circuits. To achieve this aim, we have to implement arbitrarily quantum gates on motional states of the atoms. On the other hand, as

Bennett, et al., showed in 1995, any unitary operation can be decomposed into a sequence of single-qubit rotations and two-qubit CNOT gates [11]. Thus, by implementation of only these gates, we can realize arbitrary complex gates. The polarizing beam splitter (PBS), half-wave plate (HWP), and quarter-wave plate (QWP) perform operations of the two-qubit CNOT and single-qubit rotations gates. Wave plates and PBS operations on a trapped atom chip have not been implemented before, but they are needed for the realization of universal quantum gates. This work is an effort in that regard.

Here, we propose a scheme for modeling the phonon analog of optical elements including PBS, HWP, and QWP in such a way that the vibrational motion along the x - and y - axes play the role of the horizontal and vertical polarization, respectively. To this end, we consider two atoms trapped in the x - y plane, which the internal states of the atoms are taken to be Rydberg circular states. Two counter-propagating circularly polarized Laguerre–Gaussian (LG) beams illuminate selectively only one of the atoms. We show that external degrees of freedom of the atoms can be decoupled from the internal degree of the first atom by preparing the initial internal state of the first atom in $(|e\rangle + |g\rangle)/\sqrt{2}$ or $(|e\rangle + i|g\rangle)/\sqrt{2}$, and adjusting the frequency of the beams and trap. In this way we can model the PBS, HWP and QWP for the external degree of freedom of the atoms. One of interesting feature of our scheme is the exploitation of orbital angular momentum (OAM) modes of light. Actually in our model the OAM modes lead to a nonlinearity, which is needed for realizing the above-mentioned phonon analog of optical elements.

In this study we proceed as follows. In section II, we first determine evolution operators of polarization-sensitive analog optical elements, including a PBS, a HWP, and a QWP. In section III, we develop a method

† fani.m@sci.ui.ac.ir

‡ jdowling@phys.lsu.edu

§ saeidian@iasbs.ac.ir

for the realization of the PBS, HWP and QWP for phonons. In other words, we engineer a Hamiltonian corresponding to the PBS, HWP, and QWP, by using two atoms trapped in a two dimensional plane, where one of them interacts with two classical, circularly polarized LG beams. In section IV, we investigate the realization of Pauli single-qubit gates and a two-qubit CNOT gate with the trapped atom. Finally, we summarize our results and conclude with section V.

II. EVOLUTION OPERATORS OF POLARIZING OPTICAL ELEMENTS

A. Polarizing Beam Splitter

A PBS can be used for translation of spatial qubits into polarization qubits and is described by four degrees of freedom. Two of them are related to the spatial modes, and the other two are related to the polarization. In this optical element the horizontally polarized light is always transmitted, while the vertically polarized light is always reflected (Fig.1.). Namely, the transmission coefficient for the horizontal mode t_H it is one and for the vertical mode t_V it is zero, and reflection coefficient for the horizontal mode, r_H it is zero, and for vertical mode r_V it is one.

FIG. 1. (color online) Schematic diagram of PBS which transmits the horizontal polarization and reflects the vertical polarization.

So the operation of the PBS may be described by following matrix [12],

$$\begin{bmatrix} t_H & ir_H & 0 & 0 \\ ir_H & t_H & 0 & 0 \\ 0 & 0 & t_V & ir_V \\ 0 & 0 & ir_V & t_V \end{bmatrix}, \quad (1)$$

which shows that the PBS can be described by a matrix that is similar to the matrix of a CNOT gate[12]. Thus, mode transformations of a PBS may be described in the

following form (Fig.2),

$$\hat{a}_H \rightarrow \hat{c}_H = \hat{a}_H, \quad (2)$$

$$\hat{b}_H \rightarrow \hat{d}_H = \hat{b}_H, \quad (3)$$

$$\hat{a}_V \rightarrow \hat{c}_V = i\hat{b}_V, \quad (4)$$

$$\hat{b}_V \rightarrow \hat{d}_V = i\hat{a}_V, \quad (5)$$

where \hat{a} and \hat{b} denote the input modes of the PBS and \hat{c}

FIG. 2. (color online) A schematic diagram of operation of the PBS.

and \hat{c} denote the output modes of the PBS. In the following we will determine the unitary operator corresponding to the PBS. A general two-mode Hamiltonian, which can describe the creation of a photon in mode a and the annihilation of a photon in mode b , and vice versa, may be written as [13],

$$H_{\zeta, \varphi} = \hbar \zeta e^{i\varphi} \hat{a}^\dagger \hat{b} + \hbar \zeta e^{-i\varphi} \hat{a} \hat{b}^\dagger, \quad (6)$$

Under influence of this Hamiltonian the mode operators transformations are

$$\begin{aligned} e^{\frac{i}{\hbar} H t} \hat{a} e^{-\frac{i}{\hbar} H t} &= \cos(\zeta t) \hat{a} - i e^{i\varphi} \sin(\zeta t) \hat{b}, \\ e^{\frac{i}{\hbar} H t} \hat{b} e^{-\frac{i}{\hbar} H t} &= \cos(\zeta t) \hat{b} - i e^{-i\varphi} \sin(\zeta t) \hat{a}. \end{aligned} \quad (7)$$

If we set $\zeta t = \pi/2$ and $\varphi = 0$, the unitary operator corresponding to this Hamiltonian will be,

$$U = e^{-i\frac{\pi}{2}(\hat{a}^\dagger \hat{b} + \hat{a} \hat{b}^\dagger)}, \quad (8)$$

which leads to the following transformations,

$$\hat{a} \rightarrow -i\hat{b}, \quad (9)$$

$$\hat{b} \rightarrow -i\hat{a}. \quad (10)$$

Therefore, the unitary operator corresponding to the PBS can be written as,

$$U = e^{-i\frac{\pi}{2}(\hat{a}_V^\dagger \hat{b}_V + \hat{a}_V \hat{b}_V^\dagger)}. \quad (11)$$

This evolution operator leads to the following transformations,

$$\hat{a}_H \rightarrow \hat{a}_H, \quad (12)$$

$$\hat{b}_H \rightarrow \hat{b}_H, \quad (13)$$

$$\hat{a}_V \rightarrow -i\hat{b}_V, \quad (14)$$

$$\hat{b}_V \rightarrow -i\hat{a}_V, \quad (15)$$

which are similar to the PBS transformations regardless of a minus sign in the third and forth transformations (which has no effect in our desired main result).

B. Wave Plates

Another important optical instrument is the wave plate. A wave plate is an optical device that alters the polarization state of a light wave traveling through it. Two common types of wave plates are the HWP and QWP. For linearly polarized light, the HWP rotates the polarization vector through an angle 2θ , where θ is the angle, which the optical axis of the material makes with the horizontal axis. For elliptically polarized light, the HWP inverts the light's handedness [13]. The QWP converts linearly polarized light into circularly polarized light and vice versa. A QWP can be used to produce elliptical polarization as well. In the following the unitary operators corresponding to these two optical elements is computed.

1. Half-Wave Plate

The mode transformations of a HWP have the following form [13],

$$\hat{a}_H \rightarrow \cos(2\theta)\hat{a}_H - i\sin(2\theta)\hat{a}_V, \quad (16)$$

$$\hat{a}_V \rightarrow -i\sin(2\theta)\hat{a}_H + \cos(2\theta)\hat{a}_V. \quad (17)$$

In the Bloch sphere, this corresponds to a rotation around the x -axis. The unitary operator corresponding to the HWP transformation can be written as follows,

$$U = e^{2i\theta(\hat{a}_V^\dagger \hat{a}_H + \hat{a}_V \hat{a}_H^\dagger)}. \quad (18)$$

A rotation over an angle θ of the HWP results in a polarization rotation over an angle 2θ (Fig.3).

FIG. 3. (color online) The operation of a HWP on a linearly polarized field. Axes parallel and perpendicular to the optical axis of the HWP are indicated by F and S , respectively. A spatial rotation over an angle θ of the wave plate induces a polarization rotation over an angle 2θ .

2. Quarter-Wave Plate

The mode transformations of QWP when optical axis of the material is in direction of the horizontal axis, have

the following form,

$$\hat{a}_H \rightarrow e^{-i\frac{\pi}{4}}\hat{a}_H, \quad (19)$$

$$\hat{a}_V \rightarrow e^{+i\frac{\pi}{4}}\hat{a}_V. \quad (20)$$

Moreover, the Hamiltonian corresponding to the general single-mode transformation may be written as [13],

$$\hat{H} = \hbar\varphi\hat{a}^\dagger\hat{a}. \quad (21)$$

This Hamiltonian leads to the following Bogoliubov transformation,

$$\hat{a} \rightarrow e^{-i\varphi}\hat{a}. \quad (22)$$

Thus the unitary operator, which describes a QWP is,

$$U = e^{i\frac{\pi}{4}[\hat{a}_V^\dagger\hat{a}_V - \hat{a}_H^\dagger\hat{a}_H]}. \quad (23)$$

In the following sections implementation of phonon analog of the PBS, HWP, and QWP for motional state of the two trapped atom would investigate.

III. REALIZATION OF PHONON ANALOGS OF PBS, HWP AND, QWP FOR TWO TRAPPED ATOMS

Besides energy and linear momentum, photons carry spin-angular momentum (SAM) and orbital-angular momentum (OAM). SAM is associated with the polarization while OAM is associated with the transverse amplitude and phase profile of the beam. In this section, we use these degrees of freedom (OAM and SAM) to model phonon analogs of PBS, HWP, and QWP for the phonons.

Let us consider two atoms trapped in an anisotropic 3D harmonic trap which is described by the potential $U(\mathbf{r}_i) = 1/2m(\omega_{x_i}^2(x_i - x_{0_i})^2 + \omega_{y_i}^2(y_i - y_{0_i})^2 + \omega_{z_i}^2z_i^2)$, where m is the mass of the atoms and x_{0_i} and y_{0_i} are minimum potential of the trapped atom i . The ω_{x_i} , ω_{y_i} and ω_{z_i} are frequencies of the trap in direction of x , y and z for the trapped atom i . We assume that the atoms are tightly confined along the z -axis ($\omega_z \gg \omega_{x,y}$) and neglect the motion along this axis, and they oscillate around (x_{0_i}, y_{0_i}) in the x - y plane. We can implement this kind of the trap by generalizing the proposed trap in [14]. In this paper it is introduced a blue detuned optical trap by using Gaussian beams propagating in direction of z and giving traps in the x - y plane for Rydberg atoms. Regarding that blue detuned traps provide the possibility of simultaneous trapping of both ground and Rydberg excited states, so they are interesting for experiments using Rydberg atoms. We refer the reader to Ref. [14] for further details about the how trapping fields interact with Rydberg excitation, temperature and so on.

We introduce new coordinates as $\hat{X} = (\hat{x}_1 + \hat{x}_2)/2$, $\hat{Y} = (\hat{y}_1 + \hat{y}_2)/2$ and $\hat{x} = (\hat{x}_2 - \hat{x}_1)/2$, $\hat{y} = (\hat{y}_2 - \hat{y}_1)/2$,

which shows the center of mass (CM) and breathing mode operators, respectively. Now consider two classical LG beams with the same amplitudes, polarizations (circular polarization), and transverse profile, but with different frequencies. Thus, the transverse electric field may be written as,

$$\mathbf{E} = U_\ell(\rho, \phi)(\hat{e}_x + i\hat{e}_y)(e^{-i\omega_1 t} + e^{-i\omega_2 t}) + \text{h.c.}, \quad (24)$$

where $U_\ell(\rho, \phi)$ is the transverse profile of LG beams which at the beam waist w_0 , is given by,

$$U_\ell(\rho, \phi) = \varepsilon_\ell \left(\frac{\rho}{w_0}\right)^{|\ell|} \exp\left(-\frac{\rho^2}{w_0^2} + i\ell\phi\right), \quad (25)$$

where ρ and ϕ are the radial and angular polar coordinates. The modes are characterized by an OAM equal to $\ell\hbar$ along the propagation axis. We let only one of the atoms, say the first atom, to be illuminated simultaneously by the two classical lasers (Fig.4). It is possible experimentally, because firstly, we choose the potential of the trap in such a way that the equilibrium position of the two atoms are spatially separated and secondly, we assumed the size of the CM mode wave function is small in comparison to the radius of the LG beams. So if the laser forms an appropriate angle with the plane that atoms are trapped, it can illuminate selectively only one of the atoms without illuminating the other one. For example this can be achieved if we apply a beam with waist size of $1.5 \mu\text{m}$ and a trap that can trap the atoms with spaces between atoms in order of millimeter [15].

FIG. 4. (color online) Interaction of two LG lights with one of the atoms confined in a transverse plane perpendicular to the beams at the waist of the beams.

The Hamiltonian of this system is given by,

$$\hat{H} = \hat{H}_0 + \hat{H}_{\text{int}}, \quad (26)$$

where

$$\begin{aligned} \hat{H}_0 = & \frac{\hbar\omega_0}{2}\hat{\sigma}_{z_1} + \hbar\nu_x\hat{a}_x^\dagger\hat{a}_x + \hbar\nu_y\hat{a}_y^\dagger\hat{a}_y \\ & + \hbar\mu_x\hat{b}_x^\dagger\hat{b}_x + \hbar\mu_y\hat{b}_y^\dagger\hat{b}_y, \end{aligned} \quad (27)$$

and

$$\hat{H}_{\text{int}} = -\hat{\mathbf{P}}_1 \cdot \mathbf{E}, \quad (28)$$

where $\hat{\sigma}_{z_i}$ is the Pauli operator of the i th atom, ω_0 is the atomic frequency, $\mu_i(\nu_i)$ is the frequency of the phonon in direction $i = x, y$ for the CM (breathing) mode and $\hat{a}_i(\hat{b}_i)$ is annihilation operator of the CM (breathing) mode in direction i . $\hat{\mathbf{P}}_1$ is the dipole moment of the first atom which is given by

$$\hat{\mathbf{P}}_1 = \frac{1}{2}e[(\hat{x}_1 + i\hat{y}_1)(\mathbf{e}_x - i\mathbf{e}_y) + (\hat{x}_1 - i\hat{y}_1)(\mathbf{e}_x + i\mathbf{e}_y)], \quad (29)$$

where \mathbf{e}_x and \mathbf{e}_y are the unit vectors along x - and y -axis. We assume the atoms to be in Rydberg circular electronic states. Because of the fact that circular states have the maximum value of the magnetic quantum number, $m = l = n - 1$, we represent $|n = m + 1, l = m, m\rangle$ with $|m\rangle$ for simplicity and we denote two levels of the our atom with $|m\rangle$ and $|m + 1\rangle$. Thus, the dipole moment in the internal circular atomic basis can be written as,

$$\begin{aligned} \hat{\mathbf{P}}_1 = & \frac{1}{2}P_m[(\mathbf{e}_x + i\mathbf{e}_y)\hat{\sigma}_{m_1} + (\mathbf{e}_x - i\mathbf{e}_y)\hat{\sigma}_{m_1}^\dagger] \\ = & \frac{1}{2}P_m[(\hat{\sigma}_{m_1} + \hat{\sigma}_{m_1}^\dagger)\mathbf{e}_x + i(\hat{\sigma}_{m_1} - \hat{\sigma}_{m_1}^\dagger)\mathbf{e}_y], \end{aligned} \quad (30)$$

where

$$e\langle m | (\hat{x}_1 - i\hat{y}_1) | m + 1 \rangle = e\langle m + 1 | (\hat{x}_1 + i\hat{y}_1) | m \rangle = P_m. \quad (31)$$

and

$$\hat{\sigma}_{m_1} = |m\rangle\langle m + 1|, \quad \hat{\sigma}_{m_1}^\dagger = |m + 1\rangle\langle m|. \quad (32)$$

Here, $\hat{\sigma}_{m_1}$ and $\hat{\sigma}_{m_1}^\dagger$ are Pauli operators of the first atom. By assuming that the size of the CM mode wave function R_0 is small compared with the radius of the LG beams w_0 , and given the fact that the CM motion is quantized, the transverse profile of the electric field at the beam waist and in the place of the first atom, for $\ell = 0, \pm 1, \pm 2, \dots$, can be written as [16],

$$\begin{aligned} U_\ell(\hat{\rho}, \hat{\phi}) = & \varepsilon_\ell \left(\frac{\hat{\rho}}{w_0}\right)^{|\ell|} \exp(i\ell\hat{\phi}) = \frac{\varepsilon_\ell}{w_0^{|\ell|}}(\hat{x}_1 \pm i\hat{y}_1)^{|\ell|} \\ = & \frac{\varepsilon_\ell}{w_0^{|\ell|}}((\hat{X} - \hat{x}) \pm i(\hat{Y} - \hat{y}))^{|\ell|} \\ = & \varepsilon_\ell[(\eta_{x_c}(\hat{a}_x^\dagger + \hat{a}_x) - \eta_{x_b}(\hat{b}_x^\dagger + \hat{b}_x)) \\ & \pm i(\eta_{y_c}(\hat{a}_y^\dagger + \hat{a}_y) - \eta_{y_b}(\hat{b}_y^\dagger + \hat{b}_y))]^{|\ell|} \end{aligned} \quad (33)$$

where $\eta_{x_c} = \sqrt{\hbar/m\mu_x w_0^2}$, $\eta_{y_c} = \sqrt{\hbar/m\mu_y w_0^2}$, $\eta_{x_b} = \sqrt{\hbar/m\nu_x w_0^2}$, $\eta_{y_b} = \sqrt{\hbar/m\nu_y w_0^2}$. The interaction Hamiltonian of this system for $\ell = 0, \pm 1, \pm 2, \dots$, is given by,

$$\begin{aligned} \hat{H}_{\text{int}} = & -\frac{\hbar}{2}\Omega_{m,\ell}[(\eta_{x_c}(\hat{a}_x^\dagger + \hat{a}_x) - \eta_{x_b}(\hat{b}_x^\dagger + \hat{b}_x)) \\ & \pm i(\eta_{y_c}(\hat{a}_y^\dagger + \hat{a}_y) - \eta_{y_b}(\hat{b}_y^\dagger + \hat{b}_y))]^{|\ell|} \\ & \times \hat{\sigma}_{m_1}^\dagger (e^{-i\omega_1 t} + e^{-i\omega_2 t}) + \text{h.c.}, \end{aligned} \quad (34)$$

where $\Omega_{m,\ell} = 2P_m \varepsilon_\ell / \hbar$, which is assumed to be equal for the two standing-wave lasers. We select two lasers with the following frequencies,

$$\omega_1 = \nu_y - \mu_y + \omega_0, \quad \omega_2 = -(\nu_y - \mu_y) + \omega_0. \quad (35)$$

Under this condition, the Hamiltonian in interaction picture for $\ell = 2$ (Fig.5), in the rotating-wave approximation, will be,

$$\hat{H}_{\text{int}} = \mp \hbar \Omega_{m,2} \eta_{y_c} \eta_{y_b} (\hat{a}_y^\dagger \hat{b}_y + \hat{a}_y \hat{b}_y^\dagger) (\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1}). \quad (36)$$

The evolution operator corresponding to this Hamiltonian is,

FIG. 5. (color online) Interaction of two LG beams with the same amplitudes, transverse profile, polarization (from the point of view of the atom) with an atom trapped in two dimensions.

nian is,

$$U = \exp[\pm i \Omega_{m,2} \eta_{y_c} \eta_{y_b} t (\hat{a}_y^\dagger \hat{b}_y + \hat{a}_y \hat{b}_y^\dagger) (\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1})]. \quad (37)$$

By preparing the initial internal state of the first atom in $(|e\rangle + |g\rangle)/\sqrt{2}$, the internal and external degrees of freedom would be decoupled. So dynamical evolution of the motional states of the atoms is decoupled from the dynamical evolution of internal states of the first atom. Moreover, the motional part of the evolution operator is similar to the evolution operator of the PBS, if we set $\Omega_{m,2} \eta_{y_c} \eta_{y_b} t = \pi/2$. This condition can be achieved and is compatible with experimental values found in the literature [17,18]. In more detail, the internal levels of the atoms are taken to be Rydberg circular states. These states are extremely long lived, with lifetimes that scale as n^5 , which are of the order of 10^{-2} s for $n = 30$, and the electric dipole moments are of the order of 10^{-27} Cm [17]. The Lamb-Dicke parameter can be of the order of 10^{-1} [18]. Therefore, a laser with an intensity of 1 Wm^2 , corresponding to a power of 10^{-6} W, can satisfy the condition $\Omega_{m,2} \eta_{y_c} \eta_{y_b} t = \pi/2$ for an interaction time 10^{-5} s. This shows that, not only the condition $\Omega_{m,2} \eta_{y_c} \eta_{y_b} t = \pi/2$ can be achieved, but also the interaction can be carried out before spontaneous emission can occur.

It is worth noting that the operators \hat{a}_x and \hat{a}_y play the analog role of \hat{a}_H and \hat{a}_V , respectively. In other words, the phonons vibrating in the direction of x (y) axis play the role of the horizontal (vertical) component of polarization. In more detail, an optical PBS reflects vertical photons and transmits horizontal photons, while under the effect of our analog PBS, the phonons of the

CM mode and breathing mode vibrating in the direction of x -axis will remain in the same mode, but the phonons of breathing mode vibrating in the direction of y -axis will change to the CM mode phonons vibrating in the direction of y -axis and vice versa.

In an other case, if we select two lasers with the following frequencies,

$$\omega_1 = \mu_x - \mu_y + \omega_0 \quad \omega_2 = -(\mu_x - \mu_y) + \omega_0, \quad (38)$$

the Hamiltonian in the interaction picture for $\ell = 2$ will be,

$$\hat{H}_{\text{int}} = \mp i \hbar \Omega_{m,2} \eta_{y_c} \eta_{x_c} (\hat{a}_x^\dagger \hat{a}_y + \hat{a}_x \hat{a}_y^\dagger) (\hat{\sigma}_{m_1}^\dagger - \hat{\sigma}_{m_1}). \quad (39)$$

The evolution operator corresponding to this Hamiltonian is,

$$U = \exp[\pm i \Omega_{m,2} \eta_{x_c} \eta_{y_c} t (\hat{a}_x^\dagger \hat{a}_y + \hat{a}_x \hat{a}_y^\dagger) (\hat{\sigma}_{m_1}^\dagger - \hat{\sigma}_{m_1})]. \quad (40)$$

In this case, by preparing the initial internal state of the first atom in $(|e\rangle + i|g\rangle)/\sqrt{2}$, the internal and external degrees of freedom would be decoupled. So dynamical evolution of the motional states of the atoms and dynamical evolution of the internal states of the first atom are decoupled. Moreover, the motional part of this evolution operator is similar to the evolution operator of a HWP; i.e. this interaction acts as a HWP for CM phonons. Actually this HWP rotates the direction of the vibration of the CM phonon, by 2θ , where, $\theta = \Omega_{m,2} \eta_{x_c} \eta_{y_c} t/2$, and can be controlled by adjusting the Lamb-Dicke parameters η_{x_c} and η_{y_c} , the coupling strength of the atom-light interaction, and the time of the interaction. These features provide good possibilities for manipulating the vibrational states of the atoms, which can find application in quantum information processing and computing.

If we select two lasers with the following frequencies,

$$\omega_1 = \nu_x - \nu_y + \omega_0 \quad \omega_2 = -(\nu_x - \nu_y) + \omega_0, \quad (41)$$

The interaction will act as a HWP for the breathing phonons.

In the case that we select two lasers with the following frequencies,

$$\omega_1 = \omega_2 \simeq \omega_0, \quad (42)$$

and suppose $\mu_i \ll \nu_i$, the interaction Hamiltonian will be,

$$\hat{H}_{\text{int}} = -\hbar \Omega_{m,2} [\eta_{x_c}^2 \hat{a}_x^\dagger \hat{a}_x - \eta_{y_c}^2 \hat{a}_y^\dagger \hat{a}_y + (\eta_{x_c}^2 - \eta_{y_c}^2)] (\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1}). \quad (43)$$

We can rewrite this Hamiltonian as,

$$\begin{aligned} \hat{H}_{\text{int}} = & -\hbar \Omega_{m,2} \left[\frac{\eta_{x_c}^2 - \eta_{y_c}^2}{2} (\hat{a}_x^\dagger \hat{a}_x + \hat{a}_y^\dagger \hat{a}_y) \right. \\ & \left. + \frac{\eta_{x_c}^2 + \eta_{y_c}^2}{2} (\hat{a}_x^\dagger \hat{a}_x - \hat{a}_y^\dagger \hat{a}_y) + (\eta_{x_c}^2 - \eta_{y_c}^2) \right] (\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1}). \end{aligned} \quad (44)$$

The evolution operator corresponding to this Hamiltonian is,

$$\begin{aligned}
 U = & \exp[(\eta_{x_c}^2 - \eta_{y_c}^2)(\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1})] \\
 & \times \exp[i\Omega_{m,2} \frac{\eta_{x_c}^2 - \eta_{y_c}^2}{2} t(\hat{a}_x^\dagger \hat{a}_x + \hat{a}_y^\dagger \hat{a}_y)(\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1})] \\
 & \times \exp[i\Omega_{m,2} \frac{\eta_{x_c}^2 + \eta_{y_c}^2}{2} t(\hat{a}_x^\dagger \hat{a}_x - \hat{a}_y^\dagger \hat{a}_y)(\hat{\sigma}_{m_1}^\dagger + \hat{\sigma}_{m_1})].
 \end{aligned} \quad (45)$$

As we see, if we prepare conditions under which $\Omega_{m,2}(\eta_{x_c}^2 + \eta_{y_c}^2)t/2 = \pi/4$ (it can be achieved correspond to experimental values that we mentioned earlier), and initial internal state of the first atom prepare in $(|e\rangle + |g\rangle)/\sqrt{2}$, the system acts as a QWP on the CM mode, irrespective the phase of $\exp[i\Omega_{m,2}(\eta_{x_c}^2 - \eta_{y_c}^2)(\hat{a}_x^\dagger \hat{a}_x + \hat{a}_y^\dagger \hat{a}_y)t/2]$. (Note that the number of phonons, $N = \hat{a}_x^\dagger \hat{a}_x + \hat{a}_y^\dagger \hat{a}_y$ is a constant of motion.) If $\mu_i \gg \nu_i$ and $\Omega_{m,2}(\eta_{x_b}^2 + \eta_{y_b}^2)t/2 = \pi/4$ the interaction acts as a QWP on the breathing phonons.

Therefore, only by adjusting the frequencies of the two LG beams (with $\ell = 2$), and the trap, one can prepare conditions such that the interaction acts as a PBS, HWP, and QWP for vibrational phonons.

IV. REALIZATION OF CNOT AND PAULI GATES

As Bennett, et al., showed in 1995, any unitary operation can be decomposed into a sequence of single-qubit rotations and two-qubit CNOT gates [11]. In this section we show how one can realize quantum CNOT and Pauli gates by using the interactions that we have investigated here.

If we encode vibrating directions (x and y) of phonons as states of the control qubit ($|0\rangle_c = |n_x = 1, n_y = 0\rangle$ and $|1\rangle_c = |n_x = 0, n_y = 1\rangle$) and the type of the phonon mode (CM or breathing) as states of the target qubit ($|0\rangle_t = |n_{CM} = 1, n_b = 0\rangle$ and $|1\rangle_t = |n_{CM} = 0, n_b = 1\rangle$), the four two-qubit input states ($|0,0\rangle_L = |n_x^c = 1, n_b^b = 0, n_y^c = 0, n_y^b = 0\rangle$, $|0,1\rangle_L = |0,1,0,0\rangle$, $|1,0\rangle_L = |0,0,1,0\rangle$, $|1,1\rangle_L = |0,0,0,1\rangle$) can be generated. In this case the PBS interaction Eq.(36) acts as a CNOT gate on these qubits (Fig. 6). In the same way, single-qubit gates such as Pauli X gate and Pauli Z gate can be realized by using HWP and QWP interactions.

Now, let us consider the preparing of the initial states and readout of the final state. To prepare the initial state, we should cool down the atom to be prepared in its motional ground state then by illuminating a photon with desired transition frequency on the atom we can excite the motional states in the breathing motion or CM motion in each of x or y directions. Regarding the readout processes, motional state of the trapped atom could be measured in two steps: at first, the external state of the atom should map into the internal state by using a

FIG. 6. (color online) a) Characterization of the two-qubit logical states. (b) The effect of the PBS interaction (36) on the input two-qubit states.

Jaynes-Cummings interaction, and then by performing a measurement on the internal states, one can determine the probability distribution of the motional state [19]. It should be noted that the decoherence processes cannot restrict the operation of the above mentioned gate, considerably. The most important decoherence effects in our system are spontaneous emission of atoms, mechanical damping and long-range Rydberg interaction. As we mentioned before, the time scale of operation of the CNOT and Pauli gates are smaller than the lifetime of the considered Rydberg atoms. Thus, we can be sure that during the interaction the spontaneous emission does not occur. Moreover, mechanical damping is of the order of several seconds, but we have estimated the duration of our scheme to be of the order of microseconds, so the mechanical damping can be neglected, too. On the other hand, long-range dipole-dipole interaction between the two Rydberg atoms can also be neglected, because it is proportional to $(1/r)^6$ and P^4 , where r is the distance between the atoms and P is the dipole moment of the atoms, respectively. The dipole moment of the Rydberg atoms is proportional to $a_0 n^2$, which a_0 is Bohr radius and n is principal quantum number. For our case the distance between the atoms is in order of millimeters and $n = 30$, so dipole-dipole interaction is in order of $10^{-1} Hz$, which when compared to coupling strength of the atom with light ($\Omega \sim 10^7 Hz$) is negligible [20].

V. CONCLUSION

In this paper we propose a scheme for modeling the phonon analog of the optical elements including, PBS, HWP, and QWP, as well as an implementation of CNOT and Pauli gates, by using two trapped atoms, which one of them interact with two circularly polarized LG beams. This implementation can find application in the manipulation of quantum states of the phonons for realization of quantum information and the quantum computing goals in integrated atom-optical circuits.
