Recently molecules involving one or more Rydberg excitations have attracted considerable attention due to their unusual properties. These include exotic adiabatic potentials, vibrational levels that reveal details of the potentials, and unexpected, large permanent electric dipole moments in homonuclear molecules. Two kinds of Rydberg molecules with distinct binding mechanisms have been observed, Rydberg-ground and Rydberg-Rydberg macrodimers. Rydberg-ground molecules, consisting of a Rydberg atom bound to a ground-state atom via a low-energy electron scattering mechanism, include the so-called trilobite molecules [1], which are due to $^3S$-wave-dominated scattering, and the butterfly molecules [2, 3], which are due to $^3P$-wave resonance. Rydberg-ground molecules have been experimentally observed for Rydberg $S$- [4, 5], $P$- [6], and $D$-states [7, 8], and for high-angular-momentum states [9–13]. Molecules consisting of two Rydberg atoms, bound by long-range electrostatic interactions, have been predicted [14] and observed [15–17]. Rydberg-Rydberg macrodimers have bond lengths $\geq 4n^2$, generally exceeding the LeRoy radius, and therefore have negligible exchange interaction. Deiglmayr et al. have prepared Cs macrodimer molecules near the $nS$-$n'F$ and $[nP]_2$ asymptotes for $22 \leq n \leq 32$ [16], and $43P$-$44S$ [17] molecules bound by long-range dipolar interaction.

Here we observe Cs $[62D_J]_2$ macrodimers on the red-detuned side of the $62D_J$ atomic resonances. We excite the molecules via two-step, two-color photoassociation using two sets of laser pulses, as sketched in Fig. 1(a). Seed Rydberg atoms, denoted as A-atoms, are resonantly excited from the ground state using a laser-pulse pair labeled A. The A-pulses are two-photon resonant with the interaction-free Rydberg level $|\psi\rangle = 62D_J$. The 510-nm component of the second laser pulse pair, labeled B, is detuned relative to that of pulse pair A by an amount equal to the molecular binding energy. The 852-nm components of pulse pairs A and B have the same frequency. The B-pulses excite Rydberg atoms close to the seed atoms (A-atoms), at a distance where metastable $[62D_J]_2$ macrodimers exist. Owing to the doubly-resonant character of this two-color photoassociation scheme, the excitation rate is greatly enhanced in comparison with that
of single-color photoassociation.

The experiment is performed in a Cs magneto-optical trap (MOT) with a temperature ~100 μK, and peak density ~10^{10} cm^{-3}. After switching off the MOT beams, we apply the photoassociation pulses A and B, as sketched in Fig. 1(a) and (b). The MOT magnetic field is always on. The timing diagram is shown in Fig. 1(c). The lower-transition laser (852 nm, Topica DLpro, ~100 kHz linewidth) is stabilized to the (6S_{1/2},F=4) \rightarrow (6P_{3/2},F=5) transition using polarization spectroscopy [18], and is shifted off-resonance from |e⟩ by 220 MHz using a double-pass acousto-optic modulator (AOM). The upper-transition laser (510 nm, Topica TA SHG110, ~1 MHz linewidth) is stabilized to a 62D_{J} Rydberg transition using a Rydberg EIT reference signal [19], and double-passed through another AOM. For the pulse pair A, the 510-nm AOM frequency is set to resonantly excite the seed Rydberg atoms (A-atoms). During the subsequent B pulse, the 510-nm AOM frequency is detuned and scanned to resonantly photoassociate the B- to the A-atoms, to form molecules. During the scan, the B-pulse laser power is held fixed using a PID [19] feedback loop that controls the RF power supplied to the 510-nm AOM. The 852-nm laser has a power of ~220 μW and Gaussian waist of ω_{510} ≃ 80 μm. The 510-nm beam has a waist ω_{510} ≃ 40 μm at the MOT center. The excitation region is surrounded by three pairs of field-compensation electrodes, which allow us to reduce stray electric fields to less than 250 mV/cm, via Stark spectroscopy. Rydberg atoms and molecules are detected using the electric-field ionization method (ionization ramp rise time 3 μs). Alternatively, ions spontaneously generated from Rydberg atoms or molecules can be extracted with a smaller electric field. The extracted ions are detected with a microchannel plate (MCP) detector. Spontaneously formed ions and field-ionized Rydberg atoms/molecules are discriminated by their time of flight. An ion lens, consisting of three potential grids along the ion path to the MCP, is used to collimate the ions onto the MCP and to thereby optimize the ion collection efficiency.

To model Rydberg-atom macrodimers, we consider the multipole interaction, \( V_{\text{int}} \), in the product space of two Rydberg atoms labeled A and B [16, 20, 21],

\[
\hat{V}_{\text{int}} = \sum_{q=2}^{q_{\text{max}}} \frac{1}{R^{q+1}} f_{\text{AB}q} \hat{Q}_{A} \hat{Q}_{B} \tag{1}
\]

\[
f_{\text{AB}q} = \frac{\left(-1\right)^{L_{B}} (L_{A} + L_{B})!}{\left[(L_{A} + \Omega)!L_{A} - \Omega)!L_{B} + \Omega)!L_{B} - \Omega)!\}
\]

where \( L_{A} \) and \( L_{B} \) are the multipole orders of atoms A and B, and \( L_{\text{\leq}} \) is the lessor of \( L_{A} \) and \( L_{B} \); both \( L_{A}, L_{B} \geq 1 \) because the atoms are neutral. For atom A, \( \hat{Q}_{A} = \sqrt{4\pi/(2L_{A} + 1)} f_{A}^{L_{A}} \hat{r}_{A} \), with radial matrix elements and spherical harmonics that depend on the Rydberg-electron position operator \( \hat{r}_{A} \). For atom B an equivalent expression applies, with Ω replaced by −Ω. The outer sum ends at a maximum order \( q_{\text{max}} \). We have tested cases up to \( q_{\text{max}} = 6 \) and found that \( q_{\text{max}} = 4 \) is sufficient to model potentials and level crossings with \( \lesssim 1 \) MHz accuracy. For \( q_{\text{max}} = 4 \), the terms included are \( dd, do, od, dh, qq, \) and \( hd \) interactions, where the first (second) letter stands for atom A (B), and \( d \) stands for dipole, \( q \) for quadrupole, \( o \) for octupole, and \( h \) for hexadecupole interaction. Single-atom basis states were limited to quantum numbers \( 56 \leq M \leq 5; \) two-body states were taken up to a maximal energy defect of 25 GHz from the \( 62D_{3/2} \) asymptote. Due to azimuthal symmetry, the sum of the \( m_{j} \) values relative to the internuclear axis, \( M = m_{jA} + m_{jB} \), is conserved. For \( M = 0 \), the number of two-body basis states is 2696. The adiabatic potentials are obtained by diagonalizing the Hamiltonian on a grid of internuclear separations, \( R \).

Figures 2(a) and 3(a) show calculated adiabatic potentials below the \( 62D_{3/2} \) asymptotes for \( J = 3/2 \) and 5/2, respectively, for \( q_{\text{max}} = 6 \), and for the relevant values of \( M \). [\( M \) = 0, 1, ... , 2J]. While most adiabatic potentials do not exhibit minima that could support bound Rydberg dimers (gray lines), all values of \( M \), except \( |M| = 2J \), support one binding potential. The binding potentials carry large oscillator strengths and exhibit minima that are up to \( \sim 22 \) MHz and \( \sim 42 \) MHz deep, for \( J = 3/2 \) and 5/2, at distances of \( \sim 2.4 \) μm. Figure 3 also shows several potentials without notable oscillator
strength that intersect with the binding potentials. Close inspection of Fig. 3(a) shows that most intersections are unresolved (non-adiabatic coupling $< 1$ MHz), except for $\approx 2$-MHz wide anti-crossings at -27 MHz in both the $M = 0$ and $M = 1$ binding potentials, a $\approx 1$-MHz wide one at $-39$ MHz in $M = 1$, and a sub-MHz wide one at $-35.5$ MHz in $M = 2$.

To test the convergence of the calculations, we have performed more calculations with larger basis sizes. We have increased the $n_{\text{eff}}$-range (up to $54.9 < n_{\text{eff}} < 64.9$), the $|m_J|$-range (up to $|m_J| \leq 7.5$), or the two-body energy-defect cutoff (up to 30 GHz). The basis sizes increased up to 9714 for $M = 2$ (corresponding to $2 \times 4857$ symmetrized two-body states). It was found that the potential minima and energies of large oscillator strengths shift by amounts up to 10 MHz, and that the increase in $|m_J|$-range had the largest effect. To achieve convergence at the high $n$-values used here, a supercomputer may be required. This is beyond the scope of the present work.

The black lines in Figs. 2(b) and 3(b) show two-color photoassociation spectra recorded below the [62D$_{5/2}$]$_2$ asymptotes. The 852-nm beam power is 210 $\mu$W, and the 510-nm powers are 5.7 mW for $J = 3/2$ and 1.2 mW for $J = 5/2$. The duration of the A-pulses is 0.5 $\mu$s for $J = 3/2$ and 0.2 $\mu$s for $J = 5/2$, and that of the B-pulses 6.0 $\mu$s for both $J$. The 510-nm powers and A-pulse durations are chosen differently to (partially) compensate the different optical excitation matrix elements for the 62D$_J$ Rydberg levels. Rydberg atoms and molecules are field-ionized and detected immediately after the B-pulses. At detunings $|W| > 10$ MHz the B-pulses only generate signal when the much shorter A-pulses are on, i. e. if the sample is seeded with A-Rydberg-atoms. This demonstrates that the doubly-resonant photoassociation procedure is very efficient in generating Rydberg-atom pairs at large detunings. It is noted that single- and two-color spectra are shown on identical scales.

The measured photoassociation signals in Figs. 2(b) and 3(b) include a structure-less part that rapidly drops off as a function of detuning; this part is attributed to van-der-Waals-type interaction at distances and conditions away from the aforementioned adiabatic-potential minima. In both $J$-cases, the measured spectra exhibit additional peaks near the minima of several of the highlighted adiabatic potentials. Most notable are the signals attributed to the $M = 3, 4$ potentials of $J = 5/2$ and the $M = 0, 1$ potentials of $J = 3/2$. These potentials also have the largest numbers of bound vibrational states, as shown next. We believe that the other potentials produce no or less significant signals because they support a lesser number of bound vibrational states ($M = 0, 1, 2$ for $J = 5/2$), or because their binding energy is so small that the signals are obscured by the atomic background signal ($M = 2$ for $J = 3/2$).

To gauge the importance of a binding potential, $V(R)$, in producing a signal indicative of metastable Rydberg dimers, the number of vibrational states below an energy $V_{\text{top}}$ can be estimated semiclassically as $N(V_{\text{top}}) = 2 \int_{R_o}^{R_i} p(R) dR / h + 1/2$, with momentum $p = \sqrt{2\mu(V_{\text{top}} - V(R))}$, inner and outer classical turning points $R_i(V_{\text{top}})$ and $R_o(V_{\text{top}})$, and effective mass $\mu = M_\text{Cs} / 2 \approx 66.5$ u. For the results given in Table I, we set $V_{\text{top}}$ equal to the energies of the aforementioned anti-crossings in the adiabatic potentials. Vibrational states above these anti-crossings are likely unstable; we assume that they decay into fast fragments that avoid detection after the fairly long B-pulse. In the cases where there are no relevant anti-crossings we set $V_{\text{top}} = V_{\text{min}} / 2$ [23]. The binding adiabatic potentials with the largest numbers of metastable vibrational states and the average density of states (DOS) are expected to produce the strongest spectroscopic signals. The results in Figs. 2 and 3 and Table I support this interpretation.

Our model also yields the two-body excitation rate of two-color photoassociation of the binary molecules (methods similar to [16, 20, 21]). Since our sample is not optically pumped nor are the atoms spatially pre-arranged, the calculated rates are averaged over a random spatial distribution of positions and angles between internuclear axis and laboratory frame (defined by laser polarizations), and summed over all $|M|$. Since $M$-values of same magnitude and opposite sign have the same spectra, the non-zero $|M|$-values are weighted twice as much as $M = 0$. Figure 4 shows comparisons between measured and calculated two-color excitation spectra on the red-detuned sides of [62D$_J$]$_2$. The structures in the calculated and measured spectra, indicative of the production of macrodimer Rydberg molecules, are in qualitative agreement for both cases of $J$.

Rydberg macrodimers are likely to undergo one or more decay processes that result in a free ion [17, 24, 25]. The dominant decay mode depends on the adiabatic potential the molecule is prepared on. Attractive adi-
TABLE I. The rows show the measured and calculated minima of the binding adiabatic potentials of Cs $[62D_j]_2$, $V_{\text{min}}$ (taken by visual inspection of Figs. 2 and 3), the energy at which the number of vibrational levels is evaluated, $V_{\text{top}}$, the number of energy levels, $N$, and the average density of states (DOS) between $V_{\text{min}}$ and $V_{\text{top}}$. Energies are in MHz, and DOS in MHz$^{-1}$.

To detect the spontaneous ion signal that results from these ionizing interactions, after photoassociation we insert a wait time, $\tau = 10 \mu s$, during which Rydberg atoms or molecules may ionize. We then apply an electric field that is less than the ionization field for the selected atomic state; the electric field is, however, sufficient to collect any spontaneously formed ions onto the MCP. This method yields a spontaneous-molecular-ionization signal with a greatly reduced single-atom background. The blue curve in Fig. 5 shows the molecular spectrum below the $[62D_{3/2}]_2$ asymptote obtained with the ion extraction method (free-ion spectrum). For comparison, we also display the molecular signal obtained with the field-ionization method (black curve) and the one-color Rydberg excitation signal (red line). The free-ion signal drops on the blue side of the atomic resonance. This is expected due to the suppression of ionization caused by repulsive van-der-Waals forces on the blue side of the resonance (see repulsive potentials close to the top of Fig. 3(a)). At large negative detunings, the free-ion signal is about half the field-ionization molecular signal. Thus, a large fraction of the Rydberg molecules excited by the A- and B-pulse sequence ionize with high probability during the waiting time (which is much shorter than the atomic lifetime). Comparison of the atomic signal with the other two curves in Fig. 5 reaffirms the high efficiency of the doubly-resonant photoassociation. In view of the absence of intersecting potentials in Fig. 2(a) we believe the rapid decay of the molecular signal is due to inter-Coulombic effects (see above). Some of the ionization signal may be due to non-adiabatic couplings to potentials associated with pair states outside the utilized basis sets. In Fig. 5, several peaks in the field-ionization signal may correspond to dips in the spontaneous ion signal; this indicates that the dips might correspond to longer-lived molecular resonances.

To investigate the lifetime of Rydberg-atom macrodimers, we keep the pulse-B detuning fixed at several predominant peaks in the field-ionization signals, and vary the wait time $\tau$ (see Fig. 1(c)). For $[62D_{3/2}]_2$, at detunings near the minima in the $M = 0$ and $M = 1$ potentials, the fractions of non-ionized...
molecules drop on time scales of $3.0 \pm 0.3 \mu s$ and $4.0 \pm 0.4 \mu s$. For $[62D_{3/2}]$, at detunings near the minima in the $M = 3$ and $M = 4$ adiabatic potentials, the $1/e$ decay times are $5.5 \pm 0.7 \mu s$ and $6.8 \pm 0.9 \mu s$. These measurements provide an initial indication for the lifetimes of $[62D_j]_2$ molecules.

In conclusion, we have studied Rydberg-atom macrodimers using two-color photoassociation. The frequency difference between the two colors yields the molecular binding energy. The measured spectra agree reasonably well with calculated molecular potentials and spectra. In the future, one may study mixed-parity states and the $[62D_j]_2$ with a reasonable fit of calculated molecular potentials and the measured spectra agree reasonably well with calculated molecular potentials and spectra. In the future, one may study mixed-parity states and the $[62D_j]_2$ with a reasonable fit of calculated molecular potentials. The results demonstrate the feasibility of using two-color photoassociation to study vacuum fluctuations [29, 30], to quench ultracold collisions [14], and to measure correlations in quantum gases [15, 31].

[22] The apparent width of the colored lines on top of the potential curves is proportional to the square-root of the oscillator strength.
[23] Molecules higher-up in energy are likely unstable due to non-adiabatic transition near the inner classical turning points and/or would be hard to discern from the atomic line.
