(Dated: June 21, 2018)

When quantum information is spread over a system through non-classical correlation, it makes retrieving information by local measurements difficult—making global measurement necessary for optimal parameter estimation. In this paper, we consider temperature estimation of a system in a Gibbs state and quantify the separation between the estimation performance of the global optimal measurement scheme and a greedy local measurement scheme by diagonal quantum discord. In a greedy local scheme, instead of global measurements, one performs sequential local measurement on subsystems, which is potentially enhanced by feed-forward communication. We show that for finite dimensional systems, diagonal discord quantifies the difference in the quantum Fisher information quantifying the precision limits for temperature estimation of these two schemes, and analytically obtain the relation in the high-temperature limit. We further verify this result by employing the examples of spins with Heisenberg’s interaction.

I. INTRODUCTION

Quantum metrology [1–3] utilizes quantum resources, such as entanglement and coherence to improve the precision of measurements beyond classical limits. The ultimate precision of estimating a parameter λ from a quantum state ρ(λ) is given by the quantum Cramer-Rao bound [4–6], which bounds the estimation variance $\delta \lambda^2 \geq 1/F(\lambda, \rho(\lambda))$, by the quantum Fisher information (QFI): $F(\lambda, \rho(\lambda)) = -2 \lim_{\epsilon \to 0} \partial^2 \epsilon \text{F}[\rho(\lambda), \rho(\lambda + \epsilon)]$, where $\text{F}[\rho, \sigma]$ is the fidelity between states $\rho, \sigma$.

Applications range from clock synchronization [7], to quantum illumination [8–10], super-dense measurement of quadratures [11–13] and range-velocity [14], distributed sensing [15–17], point separations sensing [18–21] and magnetic fields sensing [22, 23].

The most common sensing protocols aim at estimating parameters, with extension to quantum system identification, including Hamiltonian identification [24–26] and dimension estimation [27, 28]. All the schemes above can be seen as various kinds of channel parameter estimation, where the channels are given as a black-box with unknown parameters. There are however other important sensing tasks that go beyond the framework of channel parameter estimation, most notably temperature estimation.

Temperature is an essential quantity in thermodynamics. As the study of thermodynamics extends to the nanoscale, temperature estimation also requires a fully quantum treatment [29–40]. L. Correa et al. [32] showed that QFI for temperature estimation is proportional to the heat capacity $C(T)$. Then, the optimal measurement strategy involves projective measurements of the energy eigenstates, since heat capacity corresponds to energy fluctuations. Unfortunately, performing projective measurements of (global) energy eigenstates is typically hard, as eigenstates usually contain non-classical correlations among different parts of the system.

Recent works [41, 42] considered measurements on a single subsystem, finding that the local QFI [43] bounds the ultimate achievable precision. We can however expect that a more general measurement scheme, with sequential local measurements on multiple subsystems and (classical) feed-forward from previous measurements, could improve the estimate precision. This scheme still remains practical, and belongs to the class of local operation and classical communication (LOCC) [44]. A practical LOCC protocol is the greedy local scheme, where we sequentially measure each subsystem with a local optimal measurement (see Fig. 1). We call the constrained QFI of the greedy local scheme as the LOCC QFI.

For systems with classical Gibbs states, given by product states among subsystems, such local greedy schemes are optimal. However, for generic quantum systems, Gibbs states can be highly non-classical. Thus, temperature as a global property requires global measurements to be optimally estimated, while local sequential schemes cannot achieve the optimal precision due to the non-classical correlations in the system. The local QFI has been recently shown to depend on the correlation length at low temperature [45]. In a related metrology task, channel parameter estimation, the correlation metric for pure quantum states based on the local QFI was shown [46] to coincide with the geometric discord [47]. Also, the relation between the decreasing QFI due to the measurements on the total system and the disturbance has been considered [48].

In order to explore the relation between precision loss—the difference between QFI for the global measurement scheme and the LOCC QFI—and non-classical correlation more broadly, we focus on temperature estima-
FIG. 1. Greedy local scheme: We first measure a subsystem $A$ and then measure the other subsystem $B$. The measurement on $A$ is optimum in the sense of local QFI. The constrained QFI of this greedy local scheme is given as $F_{A\rightarrow B}(T) = F_A(T) + F_{B|A}(T)$, and we explore how the quantum discord $D_{A\rightarrow B}$ affects the loss of precision loss, i.e. $F_{AB}(T) - F_{A\rightarrow B}(T)$.

We focus on the high-temperature limit and analytically found that the precision loss can be exactly quantified by a quantum correlation metric in this regime, despite that entanglement or non-classical correlations are expected to play lesser roles. In addition, temperature estimation at high temperature is a practically important task as the capability of performing coherent operations at room-temperature is a desirable feature for quantum information processing devices. Also, quantum phenomena such as superconductivity [50, 51] survive at temperature as high as 165K.

In this paper, we explore the contribution of non-classical correlations to the ultimate precision limit of temperature estimation by comparing a greedy local scheme (see Fig. 1) to the optimal global measurement on the total system. We prove that for a bipartite system in the Gibbs state at high temperature, precision loss defined in terms of QFI is quantified by the diagonal discord [52], which is the upper bound of quantum discord and recently has been shown to play an important role in thermodynamic process, such as energy transport [53]. We further generalize this relation to multi-partite systems, showing that the precision loss is quantified by a multi-partite generalization of the diagonal discord.

II. THERMOMETRY IN BIPARTITE SYSTEMS

Consider temperature estimation from a Gibbs state $\rho = Z^{-1}\exp(-H/T)$ at temperature $T$, where $H$ is the Hamiltonian of the system, $Z \equiv \text{Tr}[\exp(-H/T)]$ is the partition function and we set the Boltzmann’s constant $k_B = 1$. QFI is given as [32] (see also Appendix A):

$$F(T) = C(T)/T^2.$$  \hfill (1)

Given $C(T) = \partial_T \langle H \rangle = \delta H^2/T^2$, energy measurement—projection to energy eigenstates—is optimal. However, global measurements are usually hard to implement. The more practical way is to estimate the temperature $T$ by measuring a subsystem. Suppose that a bipartite system is composed of subsystems $A$ and $B$, and we measure $A$. The local QFI $F_A(T) = F(T, \rho_A)$, where $\rho_A = \text{Tr}_B(\rho_{AB})$, quantifies the ultimate precision limit of any possible local measurement on a single subsystem $A$. Since the reduced state $\rho_A$ is usually not a Gibbs state, $F_A(T)$ does not follow Eq. (1).

In addition to measurement on a subsystem $A$, one can proceed to perform measurement on the reminder of the system, $B$, in order to estimate the temperature. In the greedy local scheme (see Fig. 1), the measurement on $A$ is the local optimum measurement operators $\{M_x\}_A$. Then, the quantum state of $B$ conditioned on measurement result $x$ is $\rho_{B|M_x} = 1/p_x \text{Tr}_A [(M_x \otimes \mathbb{I}_B) \rho_{AB} (M_x^\dagger \otimes \mathbb{I}_B)]$, with $p_x = \text{Tr} [(M_x \otimes \mathbb{I}_B) \rho_{AB} (M_x^\dagger \otimes \mathbb{I}_B)]$ the measurement probability. The conditional local QFI is given by $F_{B|M_x}(T) = F(T, \rho_{B|M_x})$ and the unconditional QFI is $F_{B|A}(T) = \sum_x p_x (T) F_{B|M_x}(T)$. Note that the measurement achieving $F_{B|M_x}(T)$ may depend on $x$: thus feedback is required. The LOCC QFI $F_{A\rightarrow B}$ from the above consecutive local optimal measurements on $A$ and $B$ quantifies the precision of the local greedy temperature measurement protocol. Then, the LOCC QFI can be written as:

$$F_{A\rightarrow B}(T) = F_A(T) + F_{B|A}(T),$$  \hfill (2)

which is derived from the additivity of Fisher information [54, 55]. (In Appendix B, we also provide our proofs.)

By definition, $F_{A\rightarrow B}(T) \leq F_{A}(T)$, with equality satisfied for $\rho_{AB}$ in a product state. Then, the precision loss $\Delta F(T) = F_{AB}(T) - F_{A\rightarrow B}(T)$ is generally related to bipartite non-classical correlations with a proper measure. Here in particular, we demonstrate a link to quantum discord.

Let $I_{AB}$ be the quantum mutual information between $A$ and $B$: $I_{AB} = S_A + S_B - S_{AB}$, where $S_i = -\text{Tr}[\rho_i \ln \rho_i]$ is the entropy of the state $\rho_i$. Suppose that we measure subsystem $A$ with projective measurements $\{\Pi^A_j\}$ (i.e. $\Pi^A_j \Pi^A_k = \delta_{jk} \Pi^A_j$). The classical correlation is defined as $J_{B|A} = S_B - \min_{\{\Pi^A_j\}} S_{B|\Pi^A_j}$, with $S_{B|\Pi^A_j} = S_{B|\Pi^A_j}$ the entropy of the post-measurement state $\rho_{B|\Pi^A_j}$. Then, the quantum discord of $\rho_{AB}$ as $A$ being measured is defined as $D_{A\rightarrow B} = I_{AB} - J_{B|A}$, or explicitly

$$D_{A\rightarrow B} = -S_{AB} + S_A + \min_{\{\Pi^A_j\}} S_{B|\Pi^A_j}.$$  \hfill (3)

Suppose that, instead of performing the minimization, we choose $\Pi^A_j \equiv |j\rangle_A \langle j|$ as the eigenbasis of $\rho_A$ in Eq. (3), i.e. $\rho_A = \sum_j r_j |j\rangle_A \langle j| = \sum_j r_j \Pi^A_j$. In this case, it becomes the diagonal discord $D_{A\rightarrow B}$ [52]. Note that diagonal discord has an alternative expression $D_{A\rightarrow B} = S_A + \min_{\{\Pi^A_j\}} S_{B|\Pi^A_j}$.
\[ \inf_{\pi_A} S(\pi_A(\rho_{AB})) - S(\rho_{AB}), \] where \( \pi_A = \sum_j \Pi^A_j \otimes 1_B \) and inf is due to possible degeneracy of the eigenbases.

In the high-temperature limit, for the finite dimensional bipartite systems in the Gibbs state at temperature \( T \), we find that the precision loss is given by

\[ \Delta F(T) = -\frac{1}{T} \partial_T D_{A\rightarrow B}(T) + \mathcal{O}(T^{-5}). \] (4)

This relation can be proved by realizing that in the high-temperature limit, the partial states are still well-approximated by the Gibbs states. Then relation Eq. (1) is still approximately valid and one can relate the local QFI to the entropy of the subsystem and thus to diagonal discord. Let us write the total Hamiltonian as

\[ H = H_A + H_B + H_{AB}, \]

where \( H_A \) and \( H_B \) are the system Hamiltonian of \( A \) and \( B \), respectively, and \( H_{AB} \) is the interaction Hamiltonian between \( A \) and \( B \). The Gibbs state of the total system is then \( \rho_{AB} = Z_{AB}^{-1} \exp(-\beta(H_A + H_B + H_{AB})) \), where \( \beta = 1/T \). From Eq. (1), since the heat capacity is given by \( C_{AB}(T) = T \partial_T S_{AB}(T) \), we can write:

\[ F_{AB}(T) = C_{AB}(T)/T^2 = (1/T) \partial_T S_{AB}(T). \] (5)

For a general finite-dimensional system, in the high-temperature limit \( \beta \ll 1 \), \( \rho_{AB} \) can be written as

\[ \rho_{AB} = \frac{1}{d_{AB}} \left( 1_{AB} - \beta \left( H - \frac{Tr[H]}{d_{AB}} \right) \right) + \mathcal{O}(\beta^2). \] (6)

Within the same approximation, the reduced state \( \rho_A = \text{Tr}_B[\rho_{AB}] \) is \( \rho_A \propto (1_{A} - \beta H_A - \Omega_A) + \mathcal{O}(\beta^2) \), where \( \Omega_A = \text{Const.} + \frac{1}{d_A} \sum_j \langle E_k(B) | H_{AB} | E_k(B) \rangle \), which is independent of the temperature \( T \) (here \( E_k, |E_k(B)\rangle \) are \( B \)'s energy eigenvalues and eigenstates). Note that when the interaction between \( A \) and \( B \) is absent, i.e. \( H_{AB} = 0 \), due to \( [H_A, H_B] = 0 \), the Gibbs’ state of the total system can be written as the product Gibbs’ state of the subsystems, which are only relevant to their system Hamiltonians. Therefore, in this case, we have \( \Omega_A = 0 \) for any temperature \( T \). In the high-temperature limit, in general, \( H_{\text{eff}}^A = H_A + \Omega_A \) behaves as an effective Hamiltonian for subsystem \( A \). Therefore, at high temperature, \( \rho_A \) is approximated by a Gibbs state, \( \rho_A \approx Z^A_\alpha^{-1} \exp(-\beta H_{\text{eff}}^A), \) with \( Z^A_\alpha = \text{Tr}[\exp(-\beta H_{\text{eff}}^A)] \). Then, the local QFI still follows Eq. (1) and can be written, within this approximation, as

\[ F_A(T) \simeq (1/T) \partial_T S_A(T). \] (7)

The measurement that saturates this local QFI is the projectors \( \Pi^A_j \) onto local eigenstates of \( \rho_A \), since they are also eigenstates of the effective Hamiltonian \( H_A + \Omega_A \).

Similar to \( \rho_A \), the conditional state \( \rho_{B|A} \) after measuring \( A \) can be also approximated by a Gibbs state, \( \rho_{B|A} \approx Z_{B|A}^{-1} \exp(-\beta H_{B|A}^\text{eff}), \) with effective Hamiltonian \( H_{B|A}^\text{eff} = H_B + \Omega_{B|A}, \) where \( \Omega_{B|A} = \text{Const.} + \langle j|H_{AB}|j \rangle \). This allows us to relate the corresponding local QFI to entropy

\[ F_{B|A}(T) \simeq (1/T) \partial_T S_{B|A}(T), \] (8)

where \( S_{B|A}(T) \) is the entropy of subsystem \( B \) after the measurement \( \Pi^A_j \). By selecting a set of projection measurements that minimize \( B \)'s entropy, we can relate the entropies to diagonal discord. More precisely, let \( \{\Pi^A_j\} \) be the set of projection measurements on subsystem \( A \) such that \( \sum_j p_j(T) S_{B|A}(T) = \min_{\{\Pi^A_j\}} \sum_j p_j(T) S_{B|A}(T) \).

From Eq. (5-8), we have

\[ -\partial_T D_{A\rightarrow B}(T) \simeq T \Delta F(T) - \sum_k \partial_T p_k(T) S_{B|A}(T). \] (9)

Note that for finite dimensional system we have (see Appendix C)

\[ (1/T) \sum_k \partial_T p_k(T) S_{B|A}(T) = \mathcal{O}(T^{-5}). \] (10)

Then we have two cases. A trivial case is when the greedy local method is asymptotically optimal at high temperature, i.e., \( \lim_{T \to \infty} \Delta F(T) / F(T) = 0 \), as the deviation \( \Delta F \) is no longer important. If instead \( \Delta F(T) / F(T) \) remains finite at high temperature, since QFI (see Appendix D)

\[ F(T) \simeq \mathcal{O}(T^{-4}), \] (11)

we must also have \( \Delta F(T) = \mathcal{O}(T^{-4}), \) which is then the dominant term in the right-hand-side of Eq. (9) and we recover Eq. (4).

We can make these ideas more concrete by presenting an example given by a two-qubit X state [56–58]. We consider the general Heisenberg’s interaction Hamiltonian \( H = (1/2) (B_1 Z_A + B_2 Z_B + J_x X_A X_B + J_y Y_A Y_B + J_z Z_A Z_B), \) where \( X_k, Y_k \) and \( Z_k \) are the Pauli’s matrices acting on \( k \)-th qubit. The Gibbs state of this system is the two-qubit X state. In the high-temperature limit, the quantum mutual information is \( -(1/T) \partial_T I_{AB}(T) = - (J_x^2 + J_y^2 + J_z^2 / 4T^4) + \mathcal{O}(T^{-5}) \) and the classical correlation \( -(1/T) \partial_T J_{B|A}(T) = J_z^2 / (4T^4) + \mathcal{O}(T^{-5}) \). We can also find an analytical expression for \( \Delta F(T) \) and \( -(1/T) \partial_T D_{A\rightarrow B} \)

\[ \Delta F(T) = (J_x^2 + J_y^2) / (4T^4) + \mathcal{O}(T^{-5}), \]

\[ -(1/T) \partial_T D_{A\rightarrow B}(T) = (J_x^2 + J_y^2) / (4T^4) + \mathcal{O}(T^{-5}), \] (12)

which agree with Eq. (4).

We note that \( \Delta F \) does not depend on \( B_1, B_2 \) and \( J_z \). This can be intuitively understood since \( J_x = J_y = 0 \) yields a classical Ising model, where the Gibbs state is a classical state with zero quantum discord. In this
LOCC QFI, i.e. \( \mathcal{F}_{\sigma_{k:1:N}|M_{1:k-1}} - \mathcal{F}_{\sigma_{k-1}:N|M_{1:k-1}} \approx -(1/T)\partial_T D_{\sigma_{k-1}:N|\sigma_{k:1:N}}, \) where \( \mathcal{F}_{\sigma_{k-1}:N|\sigma_{1:k-1}} = \mathcal{F}_{\sigma_{1:1}|M_{1:k-1}} + \mathcal{F}_{\sigma_{1:k-1}|M_{1:k-1}} \).

Now we consider the unconditional QFI \( \mathcal{F}_{\sigma_{k-1}:N|\sigma_{1:k-1}} \equiv \sum_{M_{1:k-1}} P(M_{1:k-1}) \mathcal{F}_{\sigma_{k-1}:N|\sigma_{1:k-1}}, \) we have

\[
\mathcal{F}_{\sigma_{k-1}:N|\sigma_{1:k-1}} \approx -(1/T)\partial_T D_{\sigma_{k-1}:N|\sigma_{1:k-1}},
\]

where \( D_{\sigma_{k-1}:N|\sigma_{1:k-1}} \) is defined by adding the equation above from \( k = 1 \) to \( k = N - 1 \) and noting that the difference in QFI is \( \Delta \mathcal{F}_{\sigma_{1:N}} \equiv \sum_{k=1}^{N} \mathcal{F}_{\sigma_{k-1}:N|\sigma_{1:k-1}} \).

\[
\Delta \mathcal{F}_{\sigma_{1:N}}(T) \approx -(1/T)\partial_T D_{\sigma_{1:N}}(T) + O(T^{-5}),
\]

where

\[
D_{\sigma_{1:N}}(T) = \sum_{k=1}^{N-1} D_{\sigma_{k-1}:N|\sigma_{1:k-1}}(T),
\]

is a multi-partite generalization of the bipartite diagonal discord defined in Eq. (3) with respect to the ordering \( \sigma_{1:N} \). Therefore, Eq. (13) is valid for finite dimensional systems in the Gibbs state at high temperature.

The simplicity of this expression masks the fact that \( D_{\sigma_{1:N}} \) is complicated since in each term \( D_{\sigma_{k-1}:N|\sigma_{1:k-1}} \), the optimal measurement may depend on the previous measurement results \( M_{1:k-1} \). We can still get further insight by considering systems where the optimal measurement is the same for all previous measurement results. Let \( \Pi_{\sigma_{k}} \equiv \{ |j\rangle \rho_{\sigma_{k}}(j) \} \) denote the eigenbasis of \( \rho_{\sigma_{k}} \) at step \( k \), the optimal measurement must be \( \pi_{\sigma_{k}} = \sum_{j} \Pi_{\sigma_{k}} \), yielding \( D_{\sigma_{k-1}:N|\sigma_{1:k-1}} \) is the state of the entire system.

Note that all measurements \( \pi_{\sigma_{1}}, \pi_{\sigma_{N-1}}, \ldots, \pi_{\sigma_{1}} \) commute with each other because they are on orthogonal support. Eq. (14) simplifies to

\[
D_{\sigma_{1:N}} = \sum_{k=1}^{N} S(\rho_{k}) - S(\rho_{1:N}),
\]

and the measurement order does not change the difference in QFI because each of them commute and does not depend on previous measurements.

For example, consider the three-qubit Heisenberg system: \( H = \frac{B}{2} \sum_{k=1}^{3} Z_{k} + \frac{\alpha}{2} \sum_{k=1}^{3} (X_{k}X_{k+1} + Y_{k}Y_{k+1} + \alpha Z_{k}Z_{k+1}) \). It has translational symmetry, and there are only three local measurement schemes to choose from, \( 1 \to 2 \to 3, 1 \to 3 \to 2, \) and \( 2 \to 3 \to 1 \). However, we find that all three path gives the same \( \Delta \mathcal{F} \) and diagonal discord. In the high temperature limit we find \( \Delta \mathcal{F} \approx -(1/T)\partial_T D = J^2/T^4 + O(T^{-5}) \) (see Fig. 3). Compared with Eq. (12), we find that the loss is twice of the two qubit case, which is intuitive as there are two couplings.
In conclusion, we have derived a relation between the diagonal discord and the LOCC QFI by comparing the global optimal measurement to a greedy local scheme in the high-temperature limit. We have proved that the diagonal discord quantifies the loss in temperature estimation precision due to performing a sequence of local measurements on subsystems of an arbitrary finite dimensional system. In other words, the non-classical correlation other than entanglement, such as discord, can contribute to the precision enhancement in the temperature estimation. This result demonstrates a close relation between non-classical correlations and the ultimate precision limit in temperature estimation.

The relationship between precision loss in estimating temperature and diagonal discord could be potentially verified experimentally, exploiting nanoscale quantum devices. For example, recently, the local temperature of nanowires was measured [60] through the electron energy gain and loss spectroscopy from room temperature to 1600K. In general, predicting the precision loss in local measurements could guide experimentalists to select measurement protocols with the desired performance.

Although we focused on the high-temperature limit, the exploration of the finite- and low-temperature case is an interesting open direction. Indeed, for two-qubit Heisenberg’s model, except for two analytical conditions for \(-\langle 1/T \rangle \partial_T D(T) = \Delta F_2(T) (\forall T)\) given in the main text, we also numerically observe that these two quantities are close to each other for various choices of the system parameters even at low temperature (see Appendix E). We finally note that our derivation is only valid for finite dimensional systems, the extension to infinite dimensional systems is still open, due to the difficulty in the high-temperature expansion.

Appendix A: Derivation of QFI of temperature estimation for the Gibbs state

Here, we review the derivation of QFI for the Gibbs state based on [32]. Let \(H\) be the Hamiltonian of a system thermalized at temperature \(T\). Let \(\beta\) be the inverse temperature, i.e. \(\beta = 1/T\), where we have set the Boltzmann constant as \(k_B = 1\). Then, the Gibbs state is given by:

\[
\rho(\beta) = \frac{1}{Z_\beta} e^{-\beta H},
\]

where \(Z\) is the partition function:

\[
Z_\beta = \text{Tr}( e^{-\beta H} ).
\]

Suppose that we have an error \(\epsilon\) when estimating \(\beta\). Then, the state with this error is given by:

\[
\rho(\beta + \epsilon) = \frac{1}{Z_{\beta + \epsilon}} e^{-(\beta + \epsilon) H}.
\]

Quantum Fisher information (QFI) \(F(\beta)\) to estimate \(\beta\) is defined by:

\[
F(\beta) = -2 \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} F[\rho(\beta), \rho(\beta + \epsilon)],
\]

where \(F[\rho(\beta), \rho(\beta + \epsilon)]\) is the fidelity between \(\rho(\beta)\) and \(\rho(\beta + \epsilon)\):

\[
F[\rho(\beta), \rho(\beta + \epsilon)] = \left( \text{Tr} \sqrt{\rho^{1/2}(\beta) \rho(\beta + \epsilon) \rho^{1/2}(\beta)} \right)^2.
\]
Now, let us calculate the fidelity first. The fidelity is given by:

\[ F[\rho(\beta), \rho(\beta + \epsilon)] = \left( \text{Tr} \sqrt{\rho^{1/2}(\beta) \rho(\beta + \epsilon) \rho^{1/2}(\beta)} \right)^2 \]

\[ = \frac{1}{Z_\beta Z_{\beta + \epsilon}} \left( \text{Tr} \sqrt{e^{-\frac{1}{2} \beta H} e^{-\epsilon (\beta + \epsilon) H} e^{-\frac{1}{2} \beta H}} \right)^2 \]

\[ = \frac{1}{Z_{\beta + \epsilon} Z_{\beta}} \left( \text{Tr} [e^{-(\beta + \frac{\epsilon}{2}) H}] \right)^2 \]

\[ = \frac{2^{-1} \beta^{1/2}}{Z_{\beta + \epsilon} Z_{\beta}} \]

Before calculating QFI, let us show the following fact:

\[ \lim_{\epsilon \to 0} \frac{\partial}{\partial \epsilon} Z_{\beta + \epsilon} = - \lim_{\epsilon \to 0} \text{Tr} [e^{-(\beta + \epsilon) H} H] = - \text{Tr} [e^{-\beta H} H] \]

\[ \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} Z_{\beta + \epsilon} = \lim_{\epsilon \to 0} \text{Tr} [e^{-(\beta + \epsilon) H} H^2] = \text{Tr} [e^{-\beta H} H^2] \]

\[ \lim_{\epsilon \to 0} \frac{\partial}{\partial \epsilon} Z_{\beta + \frac{\epsilon}{2}} = - \lim_{\epsilon \to 0} \text{Tr} \left[ e^{-\beta H} \frac{H^2}{4} \right] = - \frac{1}{2} \text{Tr} [e^{-\beta H} H] \]

\[ \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} Z_{\beta + \frac{\epsilon}{2}} = \lim_{\epsilon \to 0} \text{Tr} \left[ e^{-(\beta + \frac{\epsilon}{2}) H} \frac{H^2}{4} \right] = \frac{1}{4} \text{Tr} [e^{-\beta H} H^2] \]

For two functions \( f(x) \) and \( g(x) \), where \( g(x) \neq 0 \), we have:

\[ \frac{\partial^2}{\partial x^2} f^2 = \frac{\partial^2 f}{\partial x^2} f + 2 \frac{\partial f}{\partial x} f \frac{\partial^2 f}{\partial x^2} f \]

\[ + \frac{4 f}{g} \frac{\partial f}{\partial x} \left( \frac{\partial g}{\partial x} - \frac{\partial^2 f}{\partial x^2} \cdot \frac{f^2}{g^2} + \frac{2 f^2}{g^3} \frac{\partial g}{\partial x} \right)^2 \]

Therefore, if we define \( x = \epsilon, f = Z_{\beta + \frac{\epsilon}{2}} \) and \( g = Z_{\beta + \epsilon} \), we can obtain:

\[ \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} F = \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} Z_{\beta + \frac{\epsilon}{2}} Z_{\beta + \epsilon} \lim_{\epsilon \to 0} \frac{1}{Z_{\beta}} \frac{\partial^2}{\partial \epsilon^2} Z_{\beta + \epsilon} \]

\[ = - \frac{1}{2} \text{Tr} \left[ e^{\beta H} \frac{H^2}{2} \right] + \frac{1}{2} \left( \text{Tr} \left[ e^{\beta H} \right] \right)^2 \]

\[ = - \frac{1}{2} \left( \text{Tr} [\rho_{\beta} H^2] - (\text{Tr} [\rho_{\beta} H])^2 \right) \]

\[ = - \frac{1}{2} \left( \langle H^2 \rangle - \langle H \rangle^2 \right) = - \frac{1}{2} \delta H^2. \]

Therefore, QFI becomes:

\[ F(\beta) = -2 \lim_{\epsilon \to 0} \frac{\partial^2}{\partial \epsilon^2} F = \delta H^2, \]

which is the variance of the Hamiltonian. Therefore, with \( M \) copies of the system, the variance of \( \beta \) satisfies the following Cramer-Rao bound:

\[ \epsilon^2 \geq \frac{1}{M F(\beta)} = \frac{1}{M \delta H^2} \]

Since \( \beta = 1/T \), we have:

\[ \frac{\epsilon}{\delta T} = \frac{\delta \beta}{\delta T} = - \frac{1}{T^2}, \]

therefore, we can obtain:

\[ \delta T^2 \geq \frac{T^4}{M \delta H^2} \]

Therefore, we can find that QFI to estimate the temperature \( T \) can be written as

\[ F(T) = \frac{\delta H^2}{T^4} = \frac{F(\beta)}{T^4}. \]

By definition, heat capacity \( C(T) \) is given by:

\[ C(T) = \frac{1}{T^2} \delta H^2, \]

QFI to estimate temperature \( T \) for the Gibbs state becomes:

\[ F(T) = \frac{C(T)}{T^2}. \]

Here, let us explain the reason why the energy measurement is the optimum for the Gibbs state. The measurement result is \( \langle H \rangle (T) = \text{Tr} [\rho H] \), and the the variance is \( \delta H^2 = \langle H^2 \rangle - \langle H \rangle^2 \). In the single-shot scenario, estimation variance \( \delta T \) can be written as

\[ \delta T = \frac{\delta H}{|\partial_T (\langle H \rangle)|}. \]

Here, note that for the Gibbs state,

\[ C(T) = \partial_T (\langle H \rangle) = \frac{(\delta H)^2}{T^2}, \]

we have \( \delta T = T/\sqrt{C(T)} \), so that the variance of the temperature becomes:

\[ \delta T^2 = \frac{T^2}{C(T)}. \]

Since QFI is \( F(T) = \frac{C(T)}{T^2} \), we can find that

\[ \delta T^2 = \delta T_{\text{min}}^2 = \frac{1}{F(T)}, \]

which indicates that the energy measurement is the optimum.

**Appendix B: Derivation of \( F_{A \rightarrow B}(T) \)**

QFI is simply the classical Fisher information over the optimal quantum measurement. Consider arbitrary consecutive measurement result \( (X, Y) \) on \( A \) and \( B \). Despite the quantum nature of the measurement, a classical
derivation suffices. The joint distribution is a Markovian chain $X \to Y$ and thus the joint distribution

$$P_{X,Y}(x, y; T) = P_X(x; T)P_{Y|X}(y|x; T).$$

Note the cross term $\partial_T \log P_X(x; T) \partial_T \log P_{Y|X}(y|x; T)$ integrates to zero in the second step. To obtain the last line, we have used the fact that the greedy local measurement scheme has constrained Fisher information.

**Appendix C: Proof of Eq. (10)**

Here, we consider $p_{j^*}(T)$. Let $d_A$ and $d_B$ be the dimension of the subsystem $A$ and $B$, respectively, and the dimension of the total system $d_{AB}$ is written as $d_{AB} = d_A d_B$. By definition, from Eq. (6), in the high-temperature limit, we can obtain

$$p_{j^*}(T) = \text{Tr}[(\Pi^{A}_{j^*} \otimes \mathbb{I}_B)\rho_{AB}(\Pi^{A}_{j^*} \otimes \mathbb{I}_B)] = \frac{1}{d_A} + \mathcal{O}(T^{-1}),$$

due to the fact that $\text{Tr}[\mathbb{I}_B] = d_B$.

Therefore, we have:

$$\partial_T p_{j^*}(T) = \mathcal{O}(T^{-2}).$$

Also, because $\sum_{j^*} p_{j^*}(T) = 1$, we have

$$\sum_{j^*} \partial_T p_{j^*}(T) = 0$$

and also the order of magnitude of the entropy is given by:

$$S_{B|\Pi^A_{j^*}}(T) = \ln (d_B) + \mathcal{O}(T^{-2}).$$

Therefore, we can obtain

$$\frac{1}{T} \sum_{j^*} \partial_T p_{j^*}(T) S_{B|\Pi^A_{j^*}}(T) = \frac{1}{T} \sum_{j^*} \partial_T p_{j^*}(T) \ln (d_B) + \mathcal{O}(T^{-5}) = \mathcal{O}(T^{-5}).$$

We consider the most general scenario where the measurement result is continuous. The discrete case in the main paper can be seen as a special case. The greedy local measurement scheme has constrained Fisher information

$$\mathcal{F}_{A\to B}(T) = \int dxdy P_{X,Y}(x, y; T) \left(\partial_T \log P_{X,Y}(x, y; T)\right)^2$$

$$= \int dxdy P_X(x; T) P_{Y|X}(y|x; T) \left(\partial_T \log P_X(x; T) + \partial_T \log P_{Y|X}(y|x; T)\right)^2$$

$$= \int dxdy P_X(x; T) P_{Y|X}(y|x; T) \left((\partial_T \log P_X(x; T))^2 + (\partial_T \log P_{Y|X}(y|x; T))^2\right)$$

$$= \int dx P_X(x; T) (\partial_T \log P_X(x; T))^2 + \int dx P_X(x; T) \int dy P_{Y|X}(y|x; T) (\partial_T \log P_{Y|X}(y|x; T))^2$$

$$= \mathcal{F}_A(T) + \mathcal{F}_{B|A}(T).$$

**Appendix D: Proof of Eq. (11)**

Let $H$ be the Hamiltonian for the finite dimensional system. Then, the partition function can be written as

$$Z = \text{Tr}[e^{-\beta H}] = \sum_{k=1}^{d} e^{-\beta h_k}.$$ 

where $d$ is the dimension of the Hamiltonian (i.e. number of eigenvalues of $H$), and $\{h_k\}_{k=1}^{d}$ are the eigenvalues of the Hamiltonian $H$. Then, the heat capacity $C(\beta)$ at high temperature ($\beta \ll 1$) can be written as:

$$C(\beta) = \left[\frac{1}{d} \sum_{k=1}^{d} h_k^2 - \left(\frac{1}{d} \sum_{k=1}^{d} h_k\right)^2\right] \beta^2 + \mathcal{O}(\beta^3)$$

$$= \delta h^2 \beta^2 + \mathcal{O}(\beta^3),$$

where

$$\delta h^2 = \frac{1}{d} \sum_{k=1}^{d} h_k^2 - \left(\frac{1}{d} \sum_{k=1}^{d} h_k\right)^2$$

is the variance of the eigenvalues. Since $\beta = 1/T$, we have:

$$C(T) = \frac{\delta h^2}{T^2} + \mathcal{O}(T^{-3}).$$

For the Gibbs state, QFI of estimating temperature is

$$\mathcal{F}(T) = \frac{C(T)}{T^2}.$$

Therefore, the order of magnitude of $\mathcal{F}(T)$ is

$$\mathcal{F}(T) = \mathcal{O}(T^{-4}).$$
In our approach, in the high-temperature limit, the subsystem can be regarded as the Gibbs state, $\mathcal{F}_A(T), \mathcal{F}_{B|A}(T)$ and $\mathcal{F}_{AB}(T)$ all have the order of magnitude $\mathcal{O}(T^{-4})$. Therefore, if the greedy local method is not asymptotically optimal at the high temperature, i.e.,

$$\lim_{T \to \infty} \frac{\Delta F(T)}{F(T)} > 0,$$

then we have

$$\Delta F(T) = \mathcal{O}(T^{-4}),$$

which shows that $\Delta F(T)$ is more dominant in the high-temperature limit, i.e.

$$\Delta F(T) \gg \frac{1}{T} \sum_{j} \langle T \partial_T p_j(T) S_{B|A_j}(T).$$

**Appendix E: More numerical results at low temperature**

We consider the two-qubit Heisenberg’s interaction Hamiltonian in absence of external fields

$$H = (1/2) (J + \lambda) X_A X_B + (J - \lambda) Y_A Y_B + J_z Z_A Z_B$$

To demonstrate the consistency between $\Delta F(T)$ and $-(1/T)\partial_T \mathcal{D}_{A\rightarrow B}(T)$, we plot the relative difference $|\Delta F + (1/T)\partial_T \mathcal{D}_{A\rightarrow B} / (\Delta F - (1/T)\partial_T \mathcal{D}_{A\rightarrow B})|$ in Fig. 4. We see that except for a small region, the relative difference is small for both $T/J = 0.4$ and $T/J = 2$.
