Scaling beyond two-node quantum networks using nitrogen vacancy (NV) centers in diamond is limited by the low probability of collecting zero phonon line (ZPL) photons from single centers. Here, we demonstrate GaP-on-diamond disk resonators which resonantly couple ZPL photons from single NV centers to single-mode waveguides. In these devices, the probability of a single NV center emitting a ZPL photon into the waveguide mode after optical excitation can reach 9%, due to a combination of resonant enhancement of the ZPL emission and efficient coupling between the resonator and waveguide. We verify the single-photon nature of the emission and experimentally demonstrate both high in-waveguide photon numbers and substantial Purcell enhancement for a set of devices. These devices may enable scalable integrated quantum networks based on NV centers.

The negatively charged nitrogen-vacancy (NV) center in diamond shows significant promise as a solid-state qubit register [1–3] for measurement-based quantum information processing (MBQIP)[4–6]. The computational resource in MBQIP is a network of entangled qubit registers. For NV centers, this network can be grown via single photon measurement of the NV zero-phonon line (ZPL) emission [7, 8]. Two-qubit networks of NV centers have been heralded in this manner using free-space collection optics [9, 10]. However, the demonstrated entanglement generation rate was significantly slower than the electron spin decoherence rate, and thus far too slow to allow multi-qubit entanglement. The limiting factor in reported entanglement rates is the low probability of detecting a ZPL photon upon excitation of an NV center. We will call this probability the total quantum efficiency, $\eta$. Successful entanglement is heralded by two independent ZPL photon detection events [11], and thus the entanglement generation rate scales as $\eta^2$. Low achieved $\eta$ values are primarily the result of two effects inherent to NV centers in diamond. First, the high refractive index of diamond limits free-space collection efficiency through total internal reflection. Second, phonon interactions result in only ~3% of radiative emission occurring via the ZPL transition [12–14]. Photonic device integration can mitigate both effects, providing a scalable photonics platform for building quantum networks.

In this work we demonstrate a key step toward realizing such a network in a GaP-on-diamond integrated photonics platform: the efficient optical coupling of single NV centers to single-mode waveguides. We show that the probability of emitting a ZPL photon into the guided mode after optical excitation can reach 9%. This high probability is achieved through a combination of resonant enhancement of ZPL emission via the Purcell effect [15], as well as efficient coupling between the resonant devices and waveguides. 10 out of 80 tested devices exhibited resonantly enhanced waveguide collection rates which exceed the theoretical limit for non-resonant collection. The limiting factor for yield is the NV-cavity coupling which can be readily improved with NV-cavity registration. Furthermore, the devices were fabricated on the same chip as passive integrated photonic components [16] necessary for on-chip entanglement generation networks. Combined, these results indicate the promise of the GaP-on-diamond photonics platform for scalable quantum networks.

Our platform utilizes a 125 nm thick GaP membrane to guide optical modes at the surface of the diamond chip [12, 16], taking advantage of the high refractive index of GaP ($n = 3.3$) compared to that of diamond ($n = 2.4$). This is in contrast to the more common approach utilizing the diamond itself as the waveguiding material [17]. A key advantage of the hybrid platform is fabrication scalability. Specifically, diamond waveguides require either undercutting of the diamond [18, 19] or working with thin diamond membranes on a low index substrate [20, 21]. Undercutting requires a three-dimensional dry etch, significantly constraining the device layout. Thin diamond membranes with large area and uniformity have yet to be demonstrated, resulting in poor device uniformity across a chip. On the other hand, large-area (cm-scale) highly uniform GaP membranes can be grown epitaxially and transferred to bulk single-crystal diamond chips, enabling the fabrication of large numbers of photonic devices with good cross-chip uniformity. For complex photonic circuits, additional features of the GaP-on-diamond platform include the introduction of a second-order optical non-linearity [22], which should enable active photonic routing, and sub-nm top-surface roughness suitable for the development of on-chip superconducting nanowire single-photon detectors [23–25]. The primary disadvantage associated with the hybrid-material platform is the inherently weaker...
coupling between the emitters located in the diamond and the guided optical modes primarily localized in the GaP. However, as we demonstrate below, this effect is mitigated with resonant devices of sufficiently high quality factor.

The photon-collection devices consist of near-surface NV centers evanescently coupled to the fundamental TE-polarized whispering-gallery mode of 1.3 µm-diameter disk resonators. The resonators are coupled to 150 nm-wide single-mode ridge waveguides (Fig. 1a,b). Prior to device fabrication, near-surface NV centers were created in the single-crystal electronic-grade diamond chip by nitrogen ion-implantation and annealing. A 125-nm GaP membrane was then transferred onto the diamond via epitaxial lift-off and van der Waals bonding [26]. Devices were fabricated on the resulting GaP-on-diamond chip by electron-beam lithography and reactive ion etching [27]. The resulting device cross-section is a 125 nm GaP waveguiding layer on a 600 nm diamond pedestal, with a sparse layer of NV centers (∼ 2 × 10⁹ cm⁻²) in the top 10-20 nm of the diamond. Further fabrication details are given in the Supplemental Information [28, 29].

Measurements were performed with the fabricated devices cooled to 8 K. For each device, the resonator mode was first tuned to the ZPL resonance. Tuning was accomplished via xenon gas deposition, which causes the cavity modes to red-shift and provides a wavelength tuning range of ∼2 nm. For cavity tuning measurements, the sample was excited at normal incidence and fluorescence spectra were collected from the output grating coupler as illustrated in Fig. 1a. An example tuning curve which shows clear NV-cavity coupling as the cavity is tuned to the NV ZPL resonance is shown in Fig. 2a. This initial tuning measurement was performed on approximately 80 devices expected to lie within the cavity tuning range of the ZPL wavelength, for four different excitation locations around the perimeter of each disk. In this way, a subset of devices showing coupled ZPL emission were identified for further study. Three additional types of measurement were performed on devices in this subset: photon auto-correlation (g(2)) on the grating-coupled ZPL emission to confirm the single-photon nature of the collected fluorescence, power dependence to determine saturated collection rates, and lifetime measurements to quantify the resonant enhancement of the ZPL emission. As we show below, the last two measurements enable two separate estimates of η for each device.

With a cavity mode tuned onto resonance with a selected ZPL, we first performed a g(2) measurement to verify the single-emitter nature of the source (see inset Fig. 2b). The grating-collected light was spectrally filtered around the selected ZPL wavelength before detection as depicted in Fig. 2b. The g(2) measurement was performed on 4 of the brightest devices, all showing auto-correlation dips with g(2)(0) < 0.4, indicating that in each device a majority of the collected photons are from a single emitter. Non-zero coincidence rates are the result of background fluorescence at the ZPL wavelength. This background fluorescence can be observed in the detuned-cavity spectrum (orange) in Fig. 2b.

We next measured the excitation power dependence of the waveguide-coupled ZPL photon rate to determine saturated collection rates. This measurement was performed by sweeping the excitation power and measuring the grating-coupled detection rate, again spectrally filtered around the selected ZPL. After removal of the background fluorescence, measured with the cavity mode detuned from the ZPL, the data were fit to a saturation model: γ(P) = γ_sat/(1 + P/P_sat), where γ(P) is the detection rate, γ_sat is the saturated detection rate, P is the excitation power and P_sat is the saturation power.

Power dependence data for 4 devices are shown in Fig. 3 (inset). Disk 1 shows a detected ZPL count rate of 1.2 × 10⁴ s⁻¹ after background subtraction. The fit indicates a saturated NV ZPL detection rate of 2.0 × 10⁴ s⁻¹, and a saturation power of 3.4 mW. Using the measured collection path efficiency for each device [28] and the known detector efficiency, we can estimate the saturated collection rate into the bus waveguide. In the case of Disk 1, the estimated on-chip collection rate is 2.5 × 10⁶ s⁻¹ from a single saturated NV center. Figure 3 shows a histogram of saturated on-chip collection rates for 10 devices.
FIG. 2. (a) Measured tuning curve showing two cavity modes as one is tuned onto resonance with a coupled NV center’s ZPL. (b) Grating-collected spectra with cavity tuned onto selected ZPL (blue curve) and detuned from ZPL (orange curve), with wavelength integration range used for count rate calculation indicated by shaded rectangles. Inset: photon autocorrelation measured with cavity tuned onto ZPL, with bi-exponential fit shown in red.

with values exceeding $5 \times 10^5 \text{ s}^{-1}$. We note that the estimated count rates for the three brightest devices are comparable to the best reported collection rates of NV ZPL photons into guided modes for all-diamond devices [20]. All 10 devices exhibit on-chip ZPL count rates exceeding the theoretical limit of approximately $3 \times 10^5 \text{ s}^{-1}$ in the absence of Purcell enhancement, calculated as 3% of a total saturated emission rate of $1 \times 10^7 \text{ s}^{-1}$ [30].

In order to quantify the achieved Purcell enhancement, the excited-state lifetimes of individual NV centers were measured using a directly modulated laser diode [31] with a measured fall time of 1 ns. Time-resolved measurements were taken on Disks 1-4, with the cavity on-resonance with a selected ZPL, as well as off-resonance. After careful subtraction of the background fluorescence waveform [28, 32, 33], the data were fit to exponential decay curves to obtain the lifetimes. Fig. 4 depicts measured on- and off-resonance time-resolved photoluminescence curves for Disks 1 and 2. Measured lifetimes under both resonance conditions were compared in order to determine the Purcell enhancement factor $F_P$ of a given device. In the non-resonant case, the lifetime $\tau_0$ is determined by $1/\tau_0 = \Gamma_0 = \Gamma_{ZPL} + \Gamma_{PSB}$, in which $\Gamma_{ZPL}$ ($\Gamma_{PSB}$) is the emission rate into the ZPL (phonon sidebands). In the resonant case, the lifetime $\tau_{res}$ is determined by $1/\tau_{res} = \Gamma_{res} = (1 + F_P)\Gamma_{ZPL} + \Gamma_{PSB}$. For Disk 1, the measured on-resonance lifetime of $4.7 \pm 0.4 \text{ ns}$ is significantly shorter than the off-resonance lifetime of $8.7 \pm 0.8 \text{ ns}$, with the ratio corresponding to a resonant Purcell factor of $F_P = 26$. This is close to the maximum possible $F_{P,max} \approx 30$ for this device geometry, given a measured quality factor of $Q = 8200$ [27]. We note that the off-resonance lifetimes in all four measured devices are significantly shorter than the NV lifetime in bulk diamond ($\sim 12 \text{ ns}$) [34, 35]. The shorter lifetimes are consistent with a broadband enhancement effect caused by the NV centers’ proximity to the diamond-GaP interface [28, 36].

The total quantum efficiency $\eta$ was estimated for Disks 1-4 by two different methods. In the first method, the measured on-resonance lifetime was used to estimate the total saturated emission rate, $\gamma_{tot}$ of a selected NV center [28, 37, 38]. For a saturated on-chip collection rate of $\gamma_{wg}$, $\eta_1$ is given by

$$\eta_1 = \frac{\gamma_{wg}}{\gamma_{tot}}.$$  \hspace{1cm} (1)

In the case of Disk 1, $\eta_1 \approx 9\%$. The second method uses the total quantum efficiency into the disk resonator mode, $\eta_{disk}$, calculated from the measured Purcell enhancement factor, and the disk-to-waveguide out-coupling efficiency, determined from grating-coupled
would thus limit NV-NV entanglement generation to a time \([10]\). The demonstrated collection efficiency of 9% for waveguide-coupled photons [24, 25], transmission measurements [28]. In this case,

\[
\eta_2 = \eta_{\text{out}} \eta_{\text{disk}} = \frac{\eta_{\text{out}} F_P}{F_P + \Gamma_0/\Gamma_{\text{ZPL}}},
\]

where \(\eta_{\text{out}}\) is the disk-to-waveguide out-coupling efficiency and \(\Gamma_0/\Gamma_{\text{ZPL}} \approx 30\). For Disk 1, \(\eta_2 \approx 9\%\). Table I summarizes the estimated total quantum efficiency obtained using both methods for 4 devices, showing reasonable agreement between the two.

TABLE I. Summary of key values for 4 selected devices.

We have shown that large \(\eta\) values are achievable in a GaP-on-diamond platform, using devices that can be readily integrated into larger on-chip photonic networks. A reasonable excitation repetition rate for NV-NV entanglement is 100 kHz, limited by the NV initialization time [10]. The demonstrated collection efficiency of 9% would thus limit NV-NV entanglement generation to a rate of 400 Hz, which significantly exceeds the ~1 s electron spin decoherence rate [39]. Achieving this efficiency-limited entanglement rate will require that all waveguide-coupled ZPL photons be detected and indistinguishable.

We note that the GaP-on-diamond system is compatible with waveguide-coupled superconducting detectors, a technology which has already demonstrated detection efficiencies exceeding 90% for waveguide-coupled photons [24, 25].

The demonstrated Purcell factors, as high as 26, exceed what has been achieved in all-diamond waveguide-integrated platforms [20, 40]. This suggests that the primary disadvantage of the hybrid materials system for MBQIP, namely that the emitter cannot be placed at the guided-mode maximum, can be largely overcome with continued improvements in resonator quality factor. A greater challenge for all integrated platforms is the production of indistinguishable photons. Specifically, it will be necessary to improve the spectral stability of near-surface NV centers, which currently exhibit spectral diffusion up to 10 GHz [41]. We are encouraged by recent work in improving NV spectral stability via high-temperature annealing [42] and longer-wavelength excitation [10]. Moreover, even if device-integrated NV centers do not exhibit the spectral stability observed for bulk NV centers incorporated during diamond growth, the platform is compatible with Stark tuning for both active ZPL frequency stabilization [43] and tuning to a single platform resonance [9, 44].

We conclude with an outlook for scalability. Our yield for simple photonic circuits which couple the ZPL emission from a single NV center to a single-mode waveguide, and which outperform the theoretical limit for free-space collection, exceeds 10%. This yield is predominantly limited by the yield in NV-resonator coupling, which in the short-term can be improved by increasing the density of near-surface NV centers. Longer-term, aligned implantation [45], combined with on-chip switching for device post-selection, should enable deterministic coupling of high-performing devices. For the latter approach, the second-order optical non-linearity associated with GaP can be leveraged to implement integrated electro-optic switching. Thus we believe the high total quantum efficiency \(\eta\), combined with large-scale integration demonstrated in this work, is a promising step toward quantum photonic networks in the hybrid GaP-on-diamond platform.
