(Dated: October 18, 2016)

We report the generation of an optical frequency comb in the mid-infrared with 1-GHz comb line spacing and no offset with respect to absolute zero frequency. This comb is tunable from 2.5-4.2 µm and covers a critical spectral region for important environmental and industrial applications such as molecular spectroscopy of trace gases. We obtain such a comb by highly efficient frequency conversion of a near-infrared frequency comb based on a compact diode-pumped SESAM-modelocked Yb:CALGO laser operating at 1 µm. The frequency conversion process is based on optical parametric amplification (OPA) in a periodically-poled lithium niobate (PPLN) chip containing buried waveguides fabricated by reverse proton exchange (RPE). The laser with a repetition rate of 1 GHz is the only active element of the system. It provides the pump pulses for the OPA process as well as seed photons in the range of 1.4-1.8 µm via supercontinuum generation (SCG) in a silicon nitride (Si3N4) waveguide. Both the PPLN and Si3N4 waveguides represent particularly suitable platforms for low-energy nonlinear interactions; they allow for mid-IR comb powers per comb line at the microwatt-level and signal amplification levels up to 35 dB with 2 orders of magnitude less pulse energy than reported in OPA systems using bulk devices. Based on numerical simulations, we explain how high amplification can be achieved at low energy using the interplay between mode confinement and a favorable group velocity mismatch configuration where the mid-IR pulse moves at the same velocity as the pump.

I. INTRODUCTION

The mid-infrared spectral region between 2-20 µm covers the strong vibrational transitions of a variety of molecules that play an important role in environmental, medical and industrial diagnostics. The ability to detect and quantify the presence of such molecules or to investigate their properties on a more fundamental level is thus directly linked to the availability of a light source capable of probing these transitions. Laser frequency combs, i.e. lasers whose spectra consist of a series of equally spaced discrete optical lines, combine three essential assets: the high brightness of the light leads to a high detection sensitivity, the narrow linewidth of the individual comb lines allows for high resolution measurements, while the large spectral bandwidth enables fast simultaneous detection of multiple species.

The success of optical frequency combs in the near-infrared has strongly been tied to the advancement of mode-locked lasers in that wavelength range. Well-established gain media include Ti:sapphire emitting around 800 nm, and various host crystals doped with Ytterbium (Yb) or Erbium (Er) emitting in the 1 µm and 1.5 µm region, respectively. Various approaches have recently been pursued to extend the spectral coverage of frequency combs into the mid-infrared. Direct approaches include new laser gain materials for mod-locked solid-state and fiber lasers or semiconductor devices such as quantum cascade lasers. Another approach relies on exploiting different aspects of nonlinear optics, such as supercontinuum generation (SCG) in fibers and waveguides, or Kerr comb generation in microresonators.

The challenge these approaches have in common is the difficulty to detect and control the comb offset frequency, i.e. the parameter that defines the exact position of the evenly spaced frequency comb lines on the absolute frequency axis. This problem can be circumvented by difference-frequency generation (DFG): in this nonlinear process, the low frequency part of a comb (termed “signal”) is mixed with the high frequency components (“pump”) of the same comb in a medium exhibiting a second order (χ(2)) nonlinearity, resulting in a difference-frequency comb (“idler”) which will be offset-free.

A configuration where the signal gets significantly amplified during this mixing process is known as an optical parametric amplifier (OPA). DFG and OPA-based mid-IR frequency combs have so far been demonstrated using bulk devices of various materials, such as periodically-poled lithium niobate (PPLN), GaSe, AgGaSe2, CdSIP2 and OP-GaAs. Due to the limited interaction length caused by diffraction and material dispersion, single-pass bulk OPAs typically require watt-level pump beams and several hundreds of milliwatts of initial signal power to achieve powers per comb line >1 µW in the mid-IR. Schemes based on high-
power oscillators, laser pre-amplification of pump and/or signal beams, or intracavity OPA have been demonstrated. Higher efficiencies in converting a near-IR frequency comb to the mid-IR can be obtained in a resonant cavity, i.e. by turning the OPA into an optical parametric oscillator (OPO). However, the passive comb-offset stability will be lost and instead the implementation of an active stabilization is required to eliminate the offset. The development of stabilized mid-IR frequency combs therefore benefits from a robust and compact configuration that allows for efficient frequency conversion at low energies with passive comb-offset stabilization, using a single modelocked laser oscillator as the only active medium.

Here, we demonstrate chip-scale waveguide technology as a compact low-energy platform for generating widely tunable, offset-free mid-IR frequency combs. A diode-pumped solid-state laser operating at 1 µm with repetition rate of 1 GHz serves as a single active source with two output beams. While one beam is directly used to pump an OPA process in a periodically-poled lithium niobate (PPLN) waveguide, the other is spectrally broadened in a silicon nitride (Si₃N₄) waveguide to generate signal photons in the wavelength range of 1.4-1.8 µm. The idler can be tuned from 2.5-4.2 µm by laterally translating the PPLN chip across waveguides with varying quasi-phase-matching (QPM) periods. With just 300 pJ of pump pulse energy and initial seed powers of <20 nW per comb line, we achieve microwatt-level comb line powers in the mid-IR. Compared to systems based on nonlinear fibers for SCG and bulk PPLN for the OPA process, the required pulse energy for obtaining the same power per comb line is lowered by nearly two orders of magnitude.

In the following, we will describe the details of the experimental setup, present the mid-IR comb results and explain via numerical simulations how the approach leverages favorable aspects of the waveguide dispersion in order to maximize the achievable OPA gain. Moreover, our simulations, which are in excellent agreement with our experimental results, show that waveguides offer the possibility to enter high-gain OPA regimes that are inaccessible to bulk devices at low energies. The ability to perform efficient supercontinuum-seeded frequency conversion at low pulse energies, as demonstrated and explained here, could enable a new class of multi-gigahertz conversion at low pulse energies, as demonstrated and explained here, could enable a new class of multi-gigahertz.

II. EXPERIMENTAL SETUP

The passively modelocked laser oscillator shown in Fig. (a) consists of a 2-mm-long Yb:CALGO emitting at 1053 nm and pumped at 980 nm using a spatially multimode pump diode. The laser is mode-locked with a semiconductor saturable absorber mirror (SESAM) and can produce pulses as short as 63 fs at a repetition rate of 1.025 GHz with an output power of up to 1.7 W (both output beams combined). One of the output beams is coupled into a 7.5-mm-long Si₃N₄ waveguide embedded in silicon dioxide (SiO₂). A coupled pulse energy of 40 pJ (coupling efficiency 15 %) is sufficient to obtain a supercontinuum spanning from 650 nm to 1800 nm as shown in Fig. (a). Using a long-pass filter, the spectrum is cut at 1400 nm and sent into the PPLN waveguide as a seed for the OPA process.

The PPLN waveguide chip with a dimension of 25x6x0.5 mm contains 90 waveguides fabricated by reverse proton exchange (RPE). The RPE method consists in a first step of exchanging lithium ions with protons using a diffusion process to create a region of higher refractive index capable of guiding light. In order to obtain buried waveguides that support Gaussian modes and efficient nonlinear mixing, the protons near the surface are subsequently removed in a reverse proton exchange step.

FIG. 1. Experimental setup showing the two output beams of the 1-GHz laser cavity. The negative second-order intracavity dispersion necessary to achieve soliton modelocking is provided by a Gires-Tournois-interferometer-(GTI)-type mirror. Isolators prevent potential back reflections from the waveguide facets into the laser. Grating pairs are used to compensate the isolator dispersion and additionally stretch the pulse in the OPA pump arm. (b) Sketch of the 1x1 mm chip with the 7.5-mm-long Si₃N₄ waveguide embedded in silicon dioxide (SiO₂). (c) Excerpt of the PPLN chip containing buried RPE waveguides in regions with different poling periods. The first 6.5 mm of the 2.5-mm-long chip are unpoled, and the waveguides are tapered to facilitate single-mode coupling.
The RPE waveguides used here were fabricated with a 12 µm width and an exchange depth of 2.3 µm. This depth, which is less than in typical PPLN waveguides designed for telecom applications [54], was chosen in order to guide the mid-IR wavelengths. At the input side of the waveguide, the width of the lithography mask pattern is adiabatically tapered to 2 µm to allow for efficient and single-mode coupling of the input near-IR beams. The different waveguides are periodically poled with poling periods ranging from 17-30 µm to achieve quasi-phase-matching (QPM). Coupling into both waveguides as well as beam collimation at the output is performed in free-space using anti-reflection (AR) coated lenses.

A Faraday isolator protects the laser cavity from potential back reflections from the waveguide facets. Grating pairs are used to compensate for the dispersion introduced by the isolators. Angled waveguide facets could be used in the future to eliminate the isolators. While the pulse at the input of the Si₃N₄ waveguide is recompressed to nearly transform-limited 85 fs, the pulses in the pump arm are purposely stretched to nearly 800 fs to maximize the pump-signal interaction in the PPLN waveguide. The general advantage of pump pulse stretching in a waveguide configuration is discussed in section V.

III. RESULTS

A. Amplification and Mid-IR Spectra

Amplified spectra, obtained by scanning through the waveguides with QPM periods from 24.60-26.49 µm, are shown in Fig. 2(b). With a maximum pump average power of 310 mW coupled into the PPLN waveguides, we were able to amplify the spectral region from 1.4-1.8 µm obtained by SCG in the Si₃N₄ waveguide by up to 35 dB. The corresponding mid-IR idler spectra range from 2.5-4.2 µm, with an average power reaching 10 mW at 3.5 µm (Fig. 2(c)). Given the comb line spacing of 1.025 GHz set by the laser, this corresponds to an average power per comb line of 4 µW. The DFG process leads to passive cancellation of the laser comb offset and therefore the stability of the mid-IR comb lines only depends on the stability of the laser repetition rate, thus the laser cavity length. Here sufficient stability was achieved with low-drift mirror mounts and boxing the setup. By mounting the SESAM onto a piezo actuator as described in 55, such ultrafast laser combs can be fully stabilized with a long-term stabilization loop and the comb lines can also be shifted by a desired amount.

The amplified signal spectra were recorded with a grating-based optical spectrum analyzer (OSA, Ando AQ-6315A). A Fourier-transform infrared spectrometer (FTIR, Thorlabs OSA2015) was used for the idler spectra. The path length of ~1 m between the output of the PPLN waveguide and the free-space input of the FTIR analyzer was sufficient to observe distinctive absorption features in the ambient air. By magnifying the mid-IR comb generated in the waveguide with the QPM period of 26.35 µm (Fig. 2(d)), we can clearly identify the presence of water (H₂O) and carbon dioxide (CO₂) absorption lines by comparing the spectrum recorded by the FTIR with the corresponding absorption cross sections provided by the high-resolution transmission molecular absorption (HITRAN) database.

B. Noise Analysis

The relative intensity noise (RIN) of a frequency comb is an important parameter, as it can limit the achievable signal-to-noise ratio in spectroscopic applications such as dual-comb spectroscopy [54]. In an OPA-based system, the RIN can increase during pre-amplification of pump and/or signal, nonlinear broadening steps, and the OPA process itself. RIN characterization at each stage of the setup thus helps to identify the bottlenecks and ultimately design low-noise systems. Figure 3 shows the RIN in our setup measured at baseband using appropriate photodiodes (Silicon Thorlabs PDA100-EC for 3-5 µm, InGaAs Thorlabs PDA10CS-EC for 1-1.8 µm, HgCdTe VIGO PVI-4TE-6 + MIPDC-5 for 3.5 µm) and a signal source analyzer (Agilent E5052B). The noise performance of the GHz laser oscillator is set by its multi-mode pump diode. Since no pre-amplifier was used, this noise level also corresponds to the RIN of the OPA pump.

To investigate the impact of OPA process itself, noise measurements were recorded using the waveguide that provided highest gain and absolute idler power (QPM period 25.47 µm, signal wavelength 1.50 µm). The RIN of the idler is, as expected, very similar to the RIN of the amplified signal. We however observed a noise increase of ~30 dB with respect to the pump noise level (Fig. 3).

In order to determine the origin of this noise increase, further measurements were performed. We verified that the shot noise levels, which depend on wavelength and optical power on the photodiode, were well below each of the respective RIN measurement results. The measured RIN of the supercontinuum over the full wavelength range accessible by the InGaAs photodiode (1-1.8 µm) was comparable to the GHz laser output, with the exception of white noise contributions above 100 kHz and technical noise around 100 Hz (Fig. 8 full SC). However, the RIN of the supercontinuum after a 15-nm band-pass filter centered at 1.5 µm is similar to the OPA output (Fig. 3(b) filtered SC, before OPA). This filter bandwidth was chosen to correspond to the bandwidth of the amplified signal. It is well known that the interplay of the various mechanisms responsible for spectral broadening during the SCG process can lead to strongly wavelength-dependent RIN [57], which becomes apparent when using narrow-band filters.

We can thus conclude from these observations that, despite the high gain, the OPA process itself is not adding a significant amount of noise but that the noise increase rather stems from the SCG process in the Si₃N₄-
FIG. 2. (a) Supercontinuum obtained with 40 pJ of coupled pulse energy in the Si$_3$N$_4$ waveguide. The shaded part is used as a signal input for the OPA. (b) Scan of the amplified signal spectra obtained by laterally scanning the chip across the different QPM periods, recorded with a grating-based optical spectrum analyzer (OSA). (c) Normalized mid-IR spectra recorded with a Fourier-transform infrared spectrometer (FTIR) ranging from 2.5–4.2 µm and corresponding to the amplified signal spectra shown in (b). The right axis displays the absolute power levels, with a maximum of 10 mW at 3.55 µm. The power drop near 3.45 µm is due to a slight defect in this particular waveguide, resulting in less overall transmitted power. (d) Zoom into an FTIR trace recorded with instrument-limited resolution of 3.6 GHz using the free-space port after ~1 m of propagation in air (orange) and absorption cross sections of water (dark blue) and carbon dioxide (light blue) taken from the HITRAN database.

FIG. 3. Relative intensity noise (RIN) measurements showing the influence of supercontinuum (SC) generation, supercontinuum filtering and optical parametric amplification for the waveguide where highest amplification was achieved. The root mean square (rms) RIN noise integrated over the interval [1 Hz, 3.5 MHz] is indicated in brackets for each measurement. The overall noise limit is set by the pump diode of the 1-GHz laser.

waveguide. In the experiment presented here, the supercontinuum was optimized above all for broad bandwidth and spectral coherence [52], but the RIN may be minimized further by numerically analyzing the wavelength-dependence of various noise types [58] and adapting the waveguide design accordingly.

IV. DISCUSSION

The experimental OPA results presented above exploited several advantageous properties that waveguides offer in comparison to bulk devices. Simulations in agreement with our experiments will be shown in this section, along with a general discussion on how to take advantage of those waveguide properties to achieve high gain and thus high conversion efficiency of a near-IR into a mid-IR comb.

A. Energy-Dependent Gain

For a phase-matched interaction assuming an undepleted, plane-wave pump field $E_p$ and no initial idler field ($E_i(0) = 0$), the signal field at the output of an OPA device with length $L$ can be written as [50]

$$E_s(L) = E_s(0) \cosh(\Gamma L),$$

(1)
where $\Gamma$ is the gain parameter defined as

$$\Gamma = \sqrt{\kappa_i \kappa_s} |E_p|$$

with $\kappa_j = 2\pi d_{\text{eff}}/(n_j \lambda_j)$, $j = 1, s$ (idler/signal) and where $d_{\text{eff}}$ denotes the material-dependent effective nonlinear coefficient. Assuming sufficiently long pump pulses to provide constant pump intensity for the signal pulse during their interaction, we can approximate the magnitude of the pump field $E_p$ as a function of the peak power $P_{pk} \sim U_p/\tau_p$:

$$|E_p| \sim \sqrt{\frac{2}{n_p \epsilon_0 c}} \sqrt{\frac{2U_p}{\pi w_0^2 \tau_p}}$$

($U_p$: pulse energy, $\tau_p$: pulse duration, $n_p$: refractive index, $w_0$: beam waist). To maximize the interaction in a bulk device, the diffraction length of the beam (and thus the beam radius) is often set to match the distance $L_{\text{GVM}}$ over which pump and signal pulses walk off each other due to group velocity mismatch (GVM)

$$w_0^2 k_p \approx L_{\text{GVM}} = \tau_p \left( \frac{1}{\tau_p^s} - \frac{1}{\tau_p^i} \right)^{-1}$$

where $k_p = n_p 2\pi/\lambda_p$ denotes the pump wavenumber. For a given set of phase-matched pump/signal/idler frequencies, the achievable gain can be independent of the pump pulse duration and can only be scaled via the pulse energy,

$$\Gamma L_{\text{GVM}} \sim C_{p,s,i} \sqrt{U_p} (\text{bulk})$$

with a proportionality factor $C_{p,s,i}$ containing the wavelength-dependent material properties. If the pump pulse is too short, then confocal focusing according to Eq. (3) may yield an intensity above the material damage threshold. In this case, the pump pulse can be stretched to avoid damage. However, the diffraction still limits the achievable gain according to Eq. (5). In a waveguide device however, the interaction is not limited by diffraction anymore, thus eliminating the relation imposed in Eq. (5) for the mode size as a function of GVM. The gain can now additionally be scaled via the pump pulse duration and the effective mode area $A_{\text{eff}}$, which takes into account the modal overlap inside the waveguide,

$$\Gamma L_{\text{GVM}} \sim C'_{p,s,i} \sqrt{U_p} \sqrt{\frac{\tau_p}{A_{\text{eff}}}} (\text{waveguide})$$

where $C'_{p,s,i} = C_{p,s,i} \sqrt{\pi/(2k_p(v_p^{-1} - v_s^{-1}))}$. Thus high gain can be maintained by stretching the pump pulse duration despite lowering the pulse energy. The waveguide cross-section is then chosen such as to optimize the overlap of the guided pump, signal and idler modes (see next section). Stretching our pump pulses to $\sim 800$ fs as described in the experimental section and taking advantage of the tight mode confinement provided by the PPLN waveguide thus allowed us to achieve high gain with nearly one order of magnitude less pulse energy than a best-case estimate of a bulk interaction.

**B. Pump vs. idler group velocity mismatch**

In the presence not only of GVM between pump and signal, but also of idler walk-off and group velocity dispersion of all the waves, a more general description of the OPA process is required [60]. In order to explain the gain variations observed experimentally across the broad signal spectral range, we performed numerical simulations based on a general model of the dynamics inside the PPLN waveguides. The model describes the propagation of the pump, signal, and idler pulses through the waveguide, accounting for the wavelength-dependent effective index and modal overlap coefficients in the waveguide, and includes both second- and third-order nonlinear properties of the PPLN waveguides [61, 62]. In order to determine the dispersion profile of the waveguides, we proceeded as follows: we first simulated the proton-diffusion inside the waveguide during the waveguide fabrication process, to obtain a proton concentration profile over the cross section of the waveguide [63]. Following [63], we obtained the change in refractive index as a function of wavelength and transverse position and then calculated the corresponding properties of the fundamental waveguide mode versus wavelength. These properties are reasonably accurate for IR wavelengths, but less is known about the mid-IR properties. To account for this, we applied an additional fixed offset to the effective index for the mid-IR part of the spectrum (wavelengths $>2\mu$m). This offset is chosen such that the numerically predicted set of phase-matched signal wavelength versus QPM period is in good agreement with the experimentally measured dependence. As can be seen in Fig. 4(a), we also included the change in refractive index induced by OH-absorption in the material around 2.85 $\mu$m [61]. Having calculated the spatial profile of the fundamental mode, an effective area for the OPA process can be defined,

$$A_{\text{eff}}(\omega_p, \omega_s) = \left\{ \int_{-\infty}^{0} \int_{-\infty}^{\infty} \tilde{d}(x,y) \times B(x,y,\omega_p)B(x,y,\omega_s) B(x,y,\omega_p - \omega_s) \, dx \, dy \right\}^{-2}$$

where $\tilde{d}$ is a normalized nonlinear coefficient accounting for the so-called ‘dead layer” (layer at the top of the waveguide, where the second-order susceptibility is erased during fabrication) [54], and $B(x,y,\omega)$ is the spatial profile of the fundamental waveguide mode with frequency $\omega$, normalized according to $\int_{-\infty}^{0} \int_{-\infty}^{\infty} |B(x,y,\omega)|^2 \, dx \, dy = 1$. An effective pump intensity, $P_{pk}/A_{\text{eff}}$, can be introduced, which leads to a normalized OPA gain rate $\gamma = \Gamma/(\sqrt{\text{pump power}})$. Figure 4(b) shows how the modal overlap integral in Eq. (7) affects the normalized gain coefficient $\gamma$ over the range of signal wavelengths used in this experiment.

In order to directly visualize the spectrally dependent effect of modal overlap and GVM on the achievable gain, the pulse propagation simulations assume a flat-top ini-
is reached in the range of 1450-1500 nm and then a decrease can be observed until the effect of the OH-absorption becomes visible for signal wavelengths around 1650-1700 nm. This trend can be explained as follows: while the gain coefficient $\gamma$ contains information about the spatial overlap of the idler with the pump and signal mode inside the waveguide, it does not take into account the temporal behavior of the idler pulses. As can be inferred from Fig. 4(a), the effective group velocity of the idler, $v_{g,\text{eff}}(\lambda_i) = c/n_{\text{group,eff}}(\lambda_i)$, crosses the velocity of the pump (intersection with red dashed line) when scanning the QPM periods. It is for the signal wavelengths corresponding to this intersection, i.e. where the idler moves at nearly the same velocity as the pump, that we observe maximum signal amplification. Figure 4 illustrates and describes the 3 regimes that we encounter in the scan:

1: At signal wavelength between 1500-1650 nm, both signal and idler propagate with a higher velocity than the pump. Although a high spatial overlap is given, the short temporal overlap inhibits further amplification (Fig. 4(a)).

2: For wavelengths around 1450-1500 nm, the corresponding idler temporally stays with the pump, leading to the build-up of a strong idler pulse and maximal signal amplification (Fig. 4(b)).

3: In the third regime (<1450 nm), signal and idler have opposite group velocities with respect to the pump (Fig. 4(c)). This configuration acts as a “trap” for the signal and idler pulses, as they are pulled towards each other, therefore ensuring a long interaction length and potentially high amplification. However, the amplification becomes highly suppressed in this wavelength range due to the increasing mode size of the idler and the resulting poor spatial overlap.

From these experimental and numerical observations, we conclude that the highest gain and thus most efficient mid-IR idler generation is achieved by designing a waveguide where the idler group velocity is as close as possible to that of the pump while maintaining a high spatial overlap.

V. CONCLUSION

In this paper, we have addressed the challenge of nonlinear optical frequency conversion at low pulse energies with the aim to transfer a 1-GHz frequency comb at 1 μm into the application-relevant mid-IR spectral region. Using a SESAM-mode-locked laser at 1 μm, we have achieved tunable offset-free combs from 2.5-4.2 μm with up to 4 μW of power per comb line around 3.5 μm. The comb spectra are generated in a PPLN RPE waveguide by optical parametric amplification. The signal photons for the OPA process are obtained by supercontinuum generation in a silicon nitride waveguide with only 40 pJ of coupled pulse energy. During the OPA stage, this signal beam is amplified by up to 35 dB using 300 pJ
of pump energy. We have shown that in contrast to bulk devices, signal amplification in a waveguide OPA can be increased by stretching the pump pulse and exploiting the waveguide dispersion to obtain a similar effective group velocity for pump and idler pulses. Those degrees of freedom provide interesting design opportunities for low-energy frequency conversion of a variety of compact laser sources, including semiconductor lasers [65], without the need for additional laser power amplifiers.
