(Dated: June 26, 2017)

We report on magnetization, magnetostriction, and magnetocaloric-effect measurements of polycrystalline  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  performed in both pulsed and static magnetic fields. Although the two compounds behave rather differently at low fields ( $\sim 5$  Tesla), they show quite similar values of the magnetocaloric effect, namely a temperature increases of about 20 K at high fields (50-60 Tesla). The magnetostriction and magnetization also reach very similar values here. We were able to quantify the magnetoelastic coupling and, based on that, applied the Bean-Rodbell criterion distinguishing first- and second-order transitions.

## INTRODUCTION

Magnetocaloric materials are the basis for a solid-state alternative to conventional compressor-based refrigeration at ambient temperature [1–4]. The rapidly developing class of magnetic refrigerators, heat pumps, and air-conditioning units based on these materials is considered to be environment-friendly, silent, compact, and energy efficient [5]. The magnetic cooling technology is based on materials exhibiting magnetic or magneto-structural phase transitions which are responsible for a large entropy change in the magnetic and structural subsystems upon application or removal of an external magnetic field. This, in turn, results in a large magnetocaloric effect (MCE) [6].

The magnetocaloric effect is defined as the change of the temperature,  $T$ , and entropy,  $S$ , caused by the variation of an applied magnetic field. Under adiabatic conditions,  $S$  remains constant and the magnetocaloric effect can be characterized quantitatively by the observed adiabatic temperature change,  $\Delta T_{ad}$ . Alternatively, by keeping  $T$  constant during a field sweep (isothermal conditions), the magnetocaloric effect results in a heat transfer,  $Q$ , between the sample and environment. Thereby,  $Q = T\Delta S_m$ , where  $\Delta S_m$  is the isothermal magnetic-entropy change [7, 8].

Both,  $\Delta T_{ad}$  and  $\Delta S_m$  comprehensively characterize magnetocaloric materials in terms of their potential application in magnetic refrigeration [9]. However, experimental data on  $\Delta T_{ad}$  are still rather scarce in literature. Mostly, the MCE is determined by measuring the isothermal,  $M(H)_T$ , or isofield,  $M(T)_H$ , magnetization with subsequent calculation of  $\Delta S_m(T)$  by using Maxwell relations.  $\Delta T_{ad}$  and  $\Delta S_m$  can also be extracted indirectly from  $S - T$  diagrams determined by use of temperature-

dependent heat-capacity data measured in different magnetic fields [10]. However, the conventional  $S - T$  diagrams describe states at thermal equilibrium, which for materials with first-order transitions are challenging to determine due to metastability and hysteresis. Since in a magnetic refrigerator the magnetocaloric materials usually are magnetized and demagnetized very quickly, the standard equilibrium  $S - T$  diagrams are only of limited use [11, 12].

Indeed, the typical thermal-cycle design frequency of a magnetic refrigerator is in the range of 1 – 10 Hz (corresponding to a magnetic-field change rate of 2 – 50 T/s), whereas in literature mainly reports on steady-field experiments are found with typical field-change rates of 0.01 T/s determined by the use of superconducting magnets. In order to determine the MCE near real operational conditions it is necessary to measure directly adiabatic temperature changes by using fast-sweeping magnets, such as standard electromagnets or assemblies of permanent magnets (e.g. nested Halbach cylinders). These allow to measure  $\Delta T_{ad}$  at frequencies up to 1 Hz with magnetic-field changes of up to 2 T/s [13, 14].

In this work, we report on measurements of  $\Delta T_{ad}$  in pulsed magnetic fields which provide us with a comprehensive access to the dynamic MCE and the high-field properties of materials with first- and second-order transitions. This allows to investigate dynamic effects of magnetic refrigerants with relevant frequencies. Non-destructive pulsed magnets have typical pulse durations of 10 – 100 ms, which perfectly match the envisioned operation frequencies of magnetic refrigerators. Thereby, the magnetic-field change can be as fast as 1000 T/s.

Another important issue we are addressing in this manuscript is tuning the system between first- and second-order transitions. Often phase transitions from

the paramagnetic (PM) to the ferromagnetic (FM) state are of second-order. Such reversible transitions are accompanied by rather modest magnetocaloric effects. In contrast, some materials show first-order transitions when entering the FM state in applied magnetic fields. Thereby, abrupt volume changes occur at the critical temperature, resulting in rapid magnetization changes. As a result, large field-induced heating and cooling effects are observable which make these materials very promising magnetocaloric refrigerants.

The big advantage of materials with first-order transitions is the relatively small magnetic field needed for switching between the PM and FM states. This allows the usage of permanent magnets in magnetic-cooling devices. On the other hand, a severe drawback is the thermal and magnetic hysteresis at the first-order transition. This drastically reduces the MCE when applying fields under cycling conditions [11, 15–17]. Strong research efforts are directed towards materials design leading to reduced hysteresis.

In some materials we can shift the transition from first to second order by adjusting their composition slightly. An important goal is to reach the tricritical point [18, 19] where the first-order transition becomes second order. This allows to utilize the entropic benefits of the first-order transition without the reduction of the MCE due to hysteretic losses.

La(Fe,Si)<sub>13</sub>-based compounds (with cubic NaZn<sub>13</sub>-type structure) are among the most promising magnetocaloric materials. They show a large magnetocaloric effect and have been widely studied in quasi-static magnetic fields from the perspective of fundamental and applied research [21–23].  $\Delta T_{ad}$ ,  $\Delta S_m$ , and the Curie temperature,  $T_C$ , of La(Fe,Si)<sub>13</sub> alloys can be widely adjusted by small additions of other elements such as H or Co. The addition of Co also alters the nature of the magnetic phase transition from first to second order. La(Fe<sub>x</sub>Si<sub>1-x</sub>)<sub>13</sub> offers a unique combination of large  $\Delta S_m$  of up to 30 JK<sup>-1</sup>kg<sup>-1</sup> in field changes of the order of 5 T coupled with remarkably small hysteresis. In this work, the alloys LaFe<sub>11.74</sub>Co<sub>0.13</sub>Si<sub>1.13</sub> and LaFe<sub>11.21</sub>Co<sub>0.65</sub>Si<sub>1.11</sub> were chosen for the investigation of the dynamic MCE in magnetic fields up to 60 T. We applied the theory proposed by Bean and Rodbell [20] to discriminate first- and second-order transitions. The Co-poor alloy shows a pronounced first-order transition at 198 K, whereas the Co-rich compound exhibits a second-order transition at 256 K.

## EXPERIMENTAL

We investigated the magnetocaloric properties of commercial samples produced by Vacuumschmelze GmbH. The LaFe<sub>11.74</sub>Co<sub>0.13</sub>Si<sub>1.13</sub> and LaFe<sub>11.21</sub>Co<sub>0.65</sub>Si<sub>1.11</sub> samples were produced using a powder metallurgical route (reactive sintering) which consists of five basic steps:

powder manufacture, powder blending, compacting, sintering, and machining [24, 25].

Measurements of  $\Delta T_{ad}$  in magnetic fields up to 1.93 T and field-sweep rates up to 2 Ts<sup>-1</sup> were performed in a dedicated experimental setup using permanent magnets in a Halbach-cylinder assembly [13]. The magnetic field was measured by a Hall probe. The temperature change of the sample was monitored with an accuracy better than  $\pm 0.01$  K using a Copper–Constantan (T-type) thermocouple. The samples were prepared as a stack of two equally shaped (0.3 × 5 × 10 mm) plates with the thermocouple placed in between. In order to reduce the influence of demagnetization effects all samples were measured with the magnetic field applied parallel to the 10 mm sample edge.

The isothermal magnetization and magnetic susceptibility up to 14 T were measured by using a physical properties measurement system (PPMS 14, Quantum Design) with vibrating sample magnetometer option.

In order to determine the compressibility, high-pressure x-ray diffraction (XRD) experiments were performed at the HP-CAT beamline 16-BM-D of the Advanced Photon Source using a Mao-type symmetric diamond anvil cell (DAC). The DAC was composed of one partially perforated diamond anvil opposing a mini-anvil mounted on a fully perforated diamond anvil with 1 mm culet diameter. A 250  $\mu$ m stainless-steel gasket was preindented to a thickness of 120  $\mu$ m and a 450  $\mu$ m diameter hole was drilled for the sample chamber. The sample was loaded into the sample chamber along with gold powder and small ruby chips, which served as pressure markers. Si oil was used as a pressure medium. Data were collected between ambient pressure and 25 kbar (2.5 GPa). Samples were measured at a wavelength of 0.41646 Å and the lattice parameters were refined using the XPGUI-GSAS software package [29].

The magnetostriction and thermal-expansion measurements in quasi-static fields were performed by using commercial strain gauges (SK-06-030TY-350, Vishay) glued to the sample surface with M-bond 610 adhesive. For better accuracy the strain gauge was connected to a Wheatstone bridge. The voltage-fed Wheatstone bridge was compensated before each measurement. Depending on the resistance change occurring in the strain gauges (due to the sample-length change) a corresponding voltage change of the bridge circuit was recorded by a DL750 oscilloscope.

Pulsed-field data were obtained at the Dresden High Magnetic Field Laboratory (HLD) [26]. The pulsed magnet used for magnetization and magnetostriction experiments can reach 60 T in about 7 ms rise time, with a total pulse duration of about 25 ms. The magnetization was measured utilizing a home-built pulsed-field magnetometer, described in [27], by integrating the voltage induced in compensated pick-up coils surrounding the sample.

The magnetostriction in pulsed magnetic fields was

measured by using an optical fiber strain gauge attached to the surface of the sample with cyanoacrylate epoxy. The strain gauge is a 1 mm long fiber Bragg grating with a peak reflectivity at 1550 nm. A sample elongation is converted to a reflectivity-peak shift, which is detected by a high-resolution grating spectrometer providing  $\Delta l/l$  resolution better than  $5 \times 10^{-7}$ . For more details see Ref. [28].

Pulsed-field magnetocaloric measurements were performed using a pulsed magnet reaching up to 50 T with 50 ms pulse duration. Thermocouple and sample mounting was similar to the static-field measurements. The sample was enclosed in a thin-walled shield, which was set under reduced pressure to provide better adiabaticity. The thermocouple signal was recorded by a storage oscilloscope.

## RESULTS

### Magnetization in static and pulsed fields

The magnetization of  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  measured in fields up to 14 T for different temperatures near the first-order transition ( $T_C = 198$  K) are shown in Fig. 1(a). A field-induced transition from the PM to FM state is visible with a clear first-order character for all temperatures above 198 K. Characteristic S-shaped magnetization curves with hysteresis between up and down sweeps are observed. The hysteresis width decreases with increasing temperature and the transition is slightly broadened. The critical field of the transition increases with temperature at a rate of 0.25 T/K.

The inset of Fig. 1(a) shows magnetization data measured in pulsed fields up to 60 T. The 7 ms duration of the up sweep is too short to keep the sample at constant temperature ensuring adiabatic conditions. Although the pulsed-field magnetization shows transitions with similar S-shapes as the static-field data, the critical fields are higher than those for the isothermal magnetization process. One pulsed-field data set with initial temperature  $T_i = 198$  K is plotted as black curve in Fig. 1(a) showing the difference between the isothermal and adiabatic magnetization data (black arrows).

This difference can be explained as follows: When the magnetic field approaches the critical value, the sample under adiabatic conditions starts heating up. The magnetization during the pulsed-field experiment then eventually reaches values of corresponding isotherms measured at  $T_i + \Delta T_{ad}$ . The latter is reflected by the length of the black arrows in Fig. 1. Comparing with  $\Delta T_{ad}$  determined in our direct MCE measurements we find a reasonable agreement.

Figure 1(b) displays the isothermal magnetization of  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ . Here, the magnetization increases smoothly with field without any sign of a first-order tran-

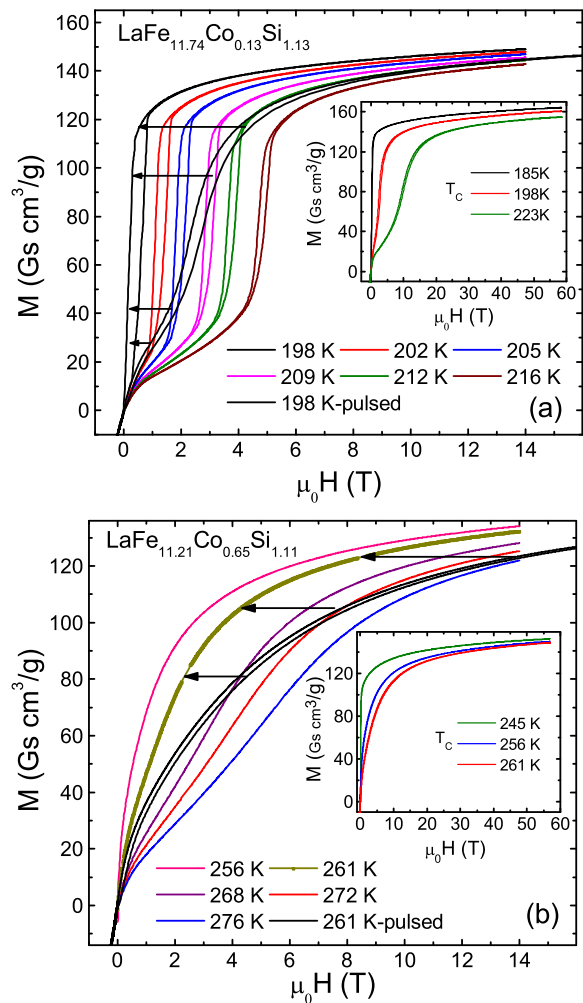

FIG. 1: Field-dependent magnetization of (a)  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and (b)  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ . Colored lines show isothermal data measured in static magnetic fields. The insets show corresponding pulsed-field magnetization curves. The arrows depict the mismatch between the isothermal and the corresponding pulsed-field data (black curves).

sition. Again, the pulsed-field data [inset of Fig. 1(b)] can be considered as adiabatic magnetization. The black arrows in Fig. 1(b) indicate the corresponding temperature increase  $\Delta T_{ad}$  that can be extracted from the isothermal magnetization. Comparison of adiabatic and isothermal magnetization curves can be used as an indirect technique for measuring the magnetocaloric effect [30].

### Direct measurements of $\Delta T_{ad}$

The inset of Fig. 2(a) shows the field-dependent  $\Delta T_{ad}$  for  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  at  $T_i = 188$  and 212 K recorded during a 10 T field pulse. Taking the values of such

FIG. 2: Adiabatic temperature change,  $\Delta T_{ad}$ , as function of initial temperature for (a)  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and (b)  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ . The black line in (a) corresponds to quasi-static measurements. The inset in (a) shows the field-dependent temperature change during 10 T field pulses for  $T_i = 188$  and  $212$  K. The inset in (b) shows the field dependence of  $\Delta T_{ad}$  for  $T_i = T_C = 256$  K.

curves (downramp) for different  $T_i$  and field-strengths the data shown in Fig. 2(a) were obtained. For 2 T,  $\Delta T_{ad}$  shows a maximum of about 8 K at  $T_i = 198$  K. For 5 and 10 T pulses, the maxima in  $\Delta T_{ad}$  of about 11 and 13 K, respectively, are reached at somewhat higher initial temperatures  $T_i$ . The black curve represents MCE data measured in quasi-static fields up to 1.8 T (Halbach setup).

The temperature dependence of  $\Delta T_{ad}$  of  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  for 4 and 6 T pulses is shown in Fig. 2(b).  $\Delta T_{ad}$  exhibits a sharp peak near  $T_C$  at 256 K with a maximum value of about 7 K (at 4 T). For 6 T pulses, the maximum in  $\Delta T_{ad}$  increases to about 9 K. The inset to the figure shows the field dependence of

FIG. 3: (a) Field dependence of  $\Delta T_{ad}$  of  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.11}$  measured in pulsed magnetic fields up to 50 T for various initial temperatures around  $T_C$ . (b) Field dependence of the sample temperature for different initial temperatures in pulsed fields.

$\Delta T_{ad}$  measured in a 50 Tesla pulse for  $T_i = T_C = 256$  K. The effect amounts to about 20 K.

Figure 3(a) shows the magnetic-field dependence of  $\Delta T_{ad}$  for  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.11}$  in pulsed magnetic fields up to 50 T for various initial temperatures. The maximum of  $\Delta T_{ad}$  is about 20 K for an initial temperature of 223 K. In order to better understand the physics behind this behavior, the data are plotted as sample temperature vs. applied magnetic field [Fig. 3(b)] [31]. The phase boundary separating the PM and FM states is drawn as dashed line. When the magnetic field is applied at temperatures above the zero-field  $T_C$  (e.g. at 212 K), first, in the PM state, the entropy changes slightly and, consequently, a small temperature increase is observed. When entering the FM state a significant sample heating occurs. Beyond this phase transition, in the FM state, again the

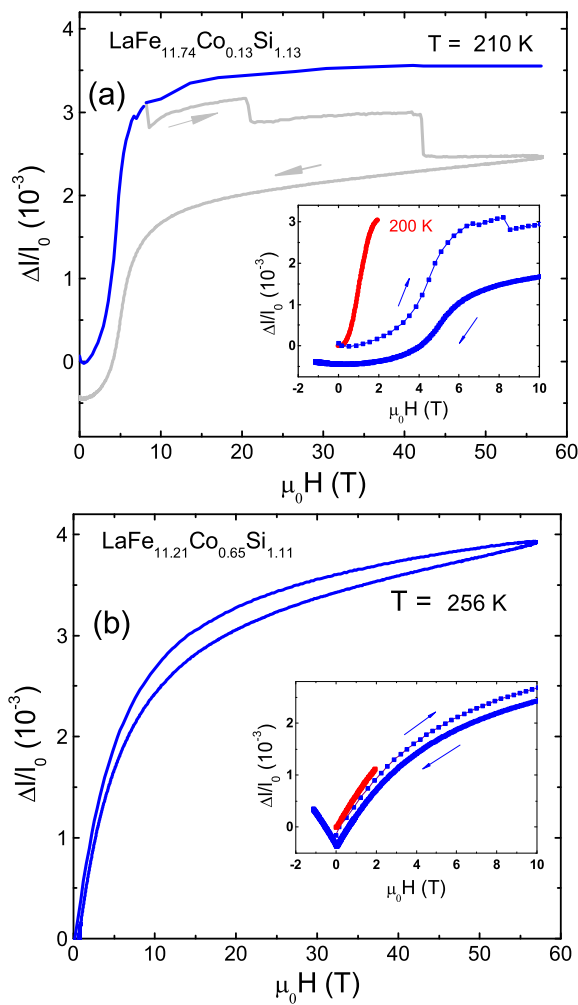

FIG. 4: Longitudinal magnetostriction,  $\Delta l/l_0$ , measured at (a) 210 K for  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and (b) 256 K for  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ . The insets display the pulsed-field data together with the static-field data.

temperature increase becomes modest.

### Magnetostriction

$\text{La}(\text{Fe},\text{Si},\text{Co})_{13}$  compounds with first-order transitions exhibit a large volume change at their phase transitions [33, 34]. This makes pulsed-field magnetostriction experiments highly challenging as the sample tends to establish cracks, even after an initial magnetization [35]. This can be ascribed not only to the volume change itself, but also to the fast field-sweep rate in pulsed magnetic fields, which increases the mechanical stress in the sample. A typical result of a pulsed-field magnetostriction experiment of a  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  sample at 210 K is shown in Fig. 4(a). (All magnetostriction measurements were performed in longitudinal configuration, i.e., with

field parallel to the length change.) The abrupt steps in  $\Delta l/l_0$  are the result of sample cracks (gray curve). The undisturbed magnetostriction is approximated by moving the affected data blocks upward (blue curve). This approach can be justified when comparing to static-field data. Magnetostriction measurements in static fields face similar difficulties due to sample cracks. However, one successful static-field measurement without the appearance of cracks is shown in the inset of Fig. 4(a). Since here the maximum field was 2 T, the measurement was performed at  $T_i = 200$  K, i.e., closer to  $T_C$ , allowing to complete the transition within the given field range. The static-field data are close to saturation at 2 T. Accordingly, the pulsed-field data at 210 K has almost reached saturation at  $\Delta l/l_0 = 0.35\%$  before the first crack appeared. This supports the reconstructed pulsed-field magnetostriction to be correct. Similar as the magnetization data, the magnetostriction shows a sharp increase due to the first-order transition with a hysteresis width of about 1.5 T. Assuming a uniform magneto-volume effect in our cubic systems [37], we estimate a volume increase of about 1%.

The longitudinal magnetostriction of  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ , on the other hand, shows a smooth increase of the sample length at 256 K [Fig. 4(b)]. This is reminiscent of the magnetization data [(Fig. 1(b))]. The maximum in  $\Delta l/l_0$  of about 0.4% is somewhat larger than for the former compound. The magnetostriction measured in pulsed and static fields for the same initial temperature show very good agreement [inset of Fig. 4(b)].

High-pressure XRD experiments were carried out on the  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  sample above its Curie temperature ( $T = 260$  K, data not shown) to obtain the sample compressibility. The fit of the pressure-dependent volume to a second order Birch-Murnaghan equation of state [32] yields  $K = (0.999 \pm 0.015) \times 10^{-12} \text{ cm}^2/\text{dyne}$ . This value was reproduced within error in independent measurements using acoustic techniques, which yielded  $K = (1.070 \pm 0.016) \times 10^{-12} \text{ cm}^2/\text{dyne}$  for the  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  sample.

### DISCUSSION

The itinerant nature of the magnetism in  $\text{La}(\text{FeCoSi})_{13}$  compounds is defined by the density of states at the Fermi level,  $N(E_F)$ . Band-structure calculations for the undoped system have been performed by Fujita et al. [39]. The different magnetic properties in the compounds is rather easy to understand qualitatively in terms of the band filling. Co has one additional 3d electron compared to Fe, so Co acts as an electron dopant. As the 3d bands are quite evolved, the additional band filling may have a complex influence on  $N(E_F)$ . If  $N(E_F)$  is large enough, the Stoner criterion is fulfilled, and the sys-

tem becomes ferromagnetic at a second-order  $T_C$ . In case the Stoner criterion is not fulfilled, but is close to that, a positive curvature of  $N(E)$  can lead to metamagnetic behavior. Our results are consistent with this scenario at low fields. Interestingly, at high fields, this difference tends to vanish. At fields of the order of 50 T, the thermodynamic properties are about equal: The magnetization of both compounds converges to about 160 Gs cm<sup>3</sup>/g,  $\Delta T_{ad}$  reaches about 20 K, and the linear magnetostriction saturates at  $\sim 0.35\%$ . Apparently, if the applied field is large enough, differences in the specific shape of  $N(E)$  are no longer important.

Obviously, the difference at low fields is due to the first-order field-induced (metamagnetic) transition, present for the Co-poor compound. The transition not only leads to the magnetization jump, but also to the huge volume increase which is inherent to the transition. Such a behavior is well described by the phenomenological theory proposed by Bean and Rodbell [20]. This theory assumes a linear dependence of  $T_C$  on the sample volume,

$$T_C = T_0(1 + \beta\omega), \quad (1)$$

where  $\omega = (V - V_0)/V_0$ . Following the notation of [20],  $T_0$  is the Curie temperature if the sample would be incompressible,  $V_0$  is the corresponding volume in the absence of exchange interactions, and  $\beta$  is the slope of the  $T_C$  dependence on volume. Minimizing the corresponding potential and setting the external pressure to zero, one obtains

$$\omega = \frac{1}{2} N K k_B T_0 \beta \left( \frac{M}{M_s} \right)^2, \quad (2)$$

where  $N$  is the number of atoms per unit volume,  $K$  is the compressibility,  $k_B$  is the Boltzmann constant, and  $M_s$  is the saturation magnetization. At this point it is worth noting that Eq. (1) is the only assumption here, no restriction has been set concerning the origin of the magnetism. Eq. (2) shows that in the framework of the Bean-Rodbell model the relative volume change  $\omega$  is proportional to the magnetization squared. The coefficient  $N K k_B T_0 \beta / (2 M_s^2)$  can then easily be found using a plot of  $\omega$  vs.  $M^2$  (Fig. 5).

In order to check the applicability of the theory we plotted  $\omega = 3\Delta l/l$  (assuming isotropic expansion) of both samples against the magnetization squared in Fig. 5. For the sample with second-order transition [Fig. 5(b)], a clear linear dependence is observed above  $T_C$ . The curve below  $T_C$  at 245 K is not linear anymore, as exchange fields should be taken into account. Some groups [39–41] point out that Eq. (2) should be extended to take into account spin fluctuations. This corrections seems to be insignificant for our discussion. The Co-poor sample with first-order transition shows as well a linear dependence in  $\omega$  vs.  $M^2$  above  $T_C$  until the metamagnetic transition appears [Fig. 5(a)]. Below  $T_C$  at 196 K again

FIG. 5: Magnetostriction vs. squared magnetization plotted for temperatures below and above  $T_C$  for (a)  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and (b)  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ .

nonlinearity is observed. These results show that in both compounds the magnetization is intrinsically connected to the expansion. This explains the concurrence of the thermodynamic parameters at high fields.

A general local-moment volume magnetostriction theory was developed by Callen and Callen [42]. They showed that the spontaneous volume magnetostriction is proportional to the squared magnetization, compressibility, and magnetovolume coupling constant  $\Gamma$ ,

$$\omega = K \Gamma M^2. \quad (3)$$

A similar equation was obtained by Shimizu [43] by extending the Wohlfarth model [44] for itinerant ferromagnets with volume-dependent terms (see also Ref. [41]). By using this approach Palstra et al. [45] report  $K\Gamma = 1.71 - 1.79 \times 10^{-8} \text{ Gs}^{-2}$  for  $\text{La}(\text{Fe}_{1-x}\text{Al}_x)_{13}$  alloys with first-order metamagnetic transitions. In our experiments, we obtain  $K\Gamma = 1.12 \times 10^{-8} \text{ Gs}^{-2}$  for

FIG. 6: Inverse magnetic susceptibility of  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  (first-order transition, FOT) and  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  (second-order transition, SOT). Dashed lines are linear extrapolations from the high-temperature data for the determination of  $T_0$ .

$\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and  $K\Gamma = 0.91 \times 10^{-8} \text{ Gs}^{-2}$  for  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  (Fig. 5).

One of the important results of the Bean-Rodbell theory is the criterion to distinguish first- and second-order transitions. If the parameter

$$\eta \equiv C_J N K k_B T_0 \beta^2 \quad (4)$$

is larger than 1, the transition is first order, for  $0 < \eta < 1$  a second-order transition is observed. It has to be mentioned, that this criterion was derived in frame of a mean-field model, where the entropy is given by the direct application of the Boltzmann definition [36]. The coefficient  $C_J$  depends on the quantum spin number  $J$ , or, otherwise, on the moment of the magnetic atom. The magnetism of our compounds is, however, clearly of itinerant nature, where a simple analytical expression of the magnetic entropy is not possible. We limit ourselves to temperatures well above  $T_C$ , where the inverse susceptibility is linear in temperature according to both itinerant and localized models.

The temperature dependence of the inverse magnetic susceptibility for both alloys are shown in Fig. 6. The extrapolated Curie-Weiss temperature  $T_0 = 256 \text{ K}$  for the material with second-order transition corresponds to the observed Curie temperature, whereas for the alloy with first-order transition  $T_0 = 125 \text{ K}$  is significantly lower than  $T_C$ . From the Curie-Weiss fits, we obtain effective moments of about  $1.4\mu_B$  per Fe atom for  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and about  $1\mu_B$  for  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$  [46]. The corresponding values of  $C_J$  are 1.3 and 0.8. From equations (2) and (4) we obtain for the compound with first-order transition  $\beta = 28$  and  $\eta = 1.2$ . This value is just above unity, which agrees with the fact that the observed hysteresis is quite narrow.

The corresponding values for the Co-rich compound are  $\beta = 10$  and  $\eta = 0.3$ . Hence, a second-order transition is expected as it is observed.

It has to be mentioned that determining of the order of the transition is possible as well by purely magnetic methods, for example using Arrott plot ( $M^2$  against  $B/M$ ) [47, 48], where the order of the transition is determined by the sign of the slope, or the sign of the  $M^4$  coefficient in the free-energy expansion. The Bean-Rodbell theory instead, takes into account the dependence of the exchange interactions on interatomic distances, and properly describes magneto-volume instabilities leading to a first-order transition. In this manner not only the order of the transition is determined, but the behavior of the system in the vicinity of the tricritical point is described.

In conclusion, we have performed magnetization, magnetostriction, and magnetocaloric-effect measurements in magnetic fields up to 60 T for  $\text{LaFe}_{11.74}\text{Co}_{0.13}\text{Si}_{1.13}$  and  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ . The former shows a first-order metamagnetic transition with abrupt increase of magnetization and volume in fields up to 5 T. The transition is accompanied by a substantial heat release.  $\text{LaFe}_{11.21}\text{Co}_{0.65}\text{Si}_{1.11}$ , on the other hand, does not show a metamagnetic behavior and, above the Curie temperature, is an ordinary paramagnet. The magnetocaloric effect reaches about 20 K at 50 Tesla in both compounds. We were able to quantify the magneto-elastic coupling and, based on that, apply the Bean and Rodbell criterion distinguishing first- and second-order transitions.

We acknowledge support from HLD at HZDR, member of the European Magnetic Field Laboratory (EMFL). O.G., A.W., and K.S. would like to acknowledge funding by the DFG in the framework of the priority program “Ferroic Cooling” (SPP1599). D. K. is grateful to the Grant in the framework of Increase Competitiveness Program of NUST “MISiS” (K4-2015-013). Work at APS was supported by the U.S. Department of Energy (DOE), Office of Science, under Contract No. DE-AC02-06CH11357. The High Pressure Collaborative Access Team (HP-CAT) operations are supported by DOE-NNSA under Award No. DE-NA0001974 and DOE-BES under Award No. DE-FG02-99ER45775, with partial instrumentation funding by the National Science Foundation. M.Z. was supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-SC0012704
