Phys. Rev. B 103, 104410 — Published 5 March 2021

DOI: 10.1103/PhysRevB.103.104410
Since the discovery of ferromagnetic two-dimensional (2D) van der Waals (vdW) crystals, significant interest on such 2D magnets has emerged, inspired by their appealing physical properties and integration with other 2D family for unique heterostructures. In known 2D magnets, spin-orbit coupling (SOC) stabilizes perpendicular magnetic anisotropy (PMA) down to one or few monolayers. Such a strong SOC could also lift the chiral degeneracy, leading to the formation of topological magnetic textures such as skyrmions through the Dzyaloshinskii-Moriya interaction (DMI). Here, we report the experimental observation of Neel-type chiral magnetic skyrmions and their lattice (SkX) formation in a vdW ferromagnet Fe₃GeTe₂ (FGT). We demonstrate the ability to drive individual skyrmion by short current pulses along a vdW heterostructure, FGT/h-BN, as highly required for any skyrmion-based spintronic device. Using first principle calculations supported by experiments, we unveil the origin of DMI being the interfaces with oxides, which then allows us to engineer vdW heterostructures for desired chiral states. Our finding opens the door to topological spin textures in the 2D vdW magnet and their potential device application.

I. INTRODUCTION

Two dimensional (2D) van der Waals (vdW) crystals have been significantly highlighted as a unique material platform, mainly due to their fascinating physical properties, low-cost fabrication and high integrability to produce appealing artificial heterostructures [1,2]. Recent addition of magnetic vdW crystals, where intrinsic long-range magnetic orders were observed in Cr₃Ge₂Te₅ and CrI₃, offered a new building block to this platform, opening a whole new door to vdW magnet-based spintronics [3–10]. Therefore, significant following interests have emerged and rapidly demonstrated few key elements for applications, including the magnetoresistance (MR) effects [5,6], gate-tunable room-temperature magnetism [7], and manipulation of magnetization switching by electrical current [11]. However, there are still some challenges for the development of vdW ferromagnet-based spintronics devices, such as rare candidates of atomic-thickness vdW ferromagnets, poor stability under ambient conditions, and low Curie temperature (usually below room temperature).

Whereas the long-range magnetic order is often suppressed in vdW crystals due to thermal fluctuations given by Mermin-Wagner theorem [12], strong spin-orbit coupling (SOC) in vdW magnets plays an essential role in
stabilizing the perpendicular magnetic anisotropy (PMA) and thus overcomes the thermal fluctuations down to a monolayer limit [4,7]. In a material with such large SOC and broken inversion symmetry, the anti-symmetric exchange interaction, so called Dzyaloshinskii-Moriya interaction (DMI) [13,14], can emerge and be strong enough to stabilize topological magnetic configurations including skyrmions [15,16]. Recent theoretical works have also discussed the emergence of DMI in vdW magnets with various possible origins, e.g. crystal symmetry or sample boundary, as well as resulting skyrmion stabilization [17–19]. Once established, by taking advantages of other 2D crystals that are stackable and offer unique electrical properties [1,2], this material platform could provide a novel route towards skyrmion-based devices that have been challenging with conventional metallic ferromagnets [20,21]. Recently, skyrmion-like spin textures have been observed experimentally in exfoliated vdW ferromagnet materials (e.g. FGT and Cr2Ge2Te6) and their heterostructures with the magnetic fields [22–26]. However, both Bloch-type and Néel-type skyrmions of the previous results have been still the subject of controversy.

In addition, experimental demonstration of their field-driven and current-driven dynamics in vdW magnets and heterostructures has remained elusive so far.

Here, we experimentally present the observation of Néel-type skyrmions and their ordered crystal structures in a vdW ferromagnetic Fe3GeTe2-based heterostructures (FGT hereafter). Moreover, we demonstrate the ability to drive skyrmions using nanoseconds current-pulses in 2D heterostructure based on FGT, i.e. FGT/h-BN. Among various types of vdW magnets, FGT exhibits relatively high ferromagnetic transition temperature (T_C), large PMA, and metallic nature that enables efficient charge/spin transport suitable for spintronic applications [7,27]. In this study, we utilize high spatial resolution magnetic imaging techniques, scanning transmission X-ray microscopy (STXM), Lorentz transmission electron microscopy (LTEM) and differential phase contrast microscopy (DPCM) to directly observe magnetic structures in the FGT-based heterostructures. We first show the dynamic generation and stabilization of skyrmion crystal (SkX, also referred to as skyrmion lattice) state in the FGT flake, where strong pulse-induced thermal
fluctuations transform magnetic domains into SkX. We then examine the stability of SkX against thermal fluctuation and magnetic fields, which eventually constitutes experimental phase diagram of SkX state. We also present the static generation of magnetic skyrmions and SkX using a tilting magnetic field, where we simultaneously unveil the Néel-type chiral nature of skyrmions stabilized in the SkX state by taking advantage of in-plane magnetization sensitivity in LTEM measurements. Moreover, we present the current-driven motion of skyrmions, where we drive isolated individual skyrmions by short current pulses along a FGT racetrack at speeds approaching a meter per second. Finally, using first principle calculations corroborated by addition DPCM measurements, we demonstrate the presence of significant interfacial DMI at FGT interfaces with oxidized layers, which then allows us to ‘engineer’ the chiral states in vdW ferromagnetic heterostructure between Bloch and Néel-types, by using selective fabrication processes.

II. RESULTS

A. Crystal structure and domain configuration

Figure 1a schematically shows the crystal structures of mono-layered FGT viewed from xy and yz planes and bi-layered FGT exhibiting vdW bonding between monolayers. Each FGT monolayer consists of a Fe₃Ge covalently bonded slab and two Te layers placed above and underneath the Fe₃Ge, and each layer is separated by a 2.95 Å vdW gap in multi-layered stack [28]. Within a Fe₃Ge slab, two inequivalent Fe sites exist, FeII (the valence states of Fe²⁺) and FeIII (the valence states of Fe³⁺), as indicated in Fig. 1a. Overall, the reduced bulk crystal symmetry in FGT is known to provide a magnetocrystalline anisotropy induced by strong SOC [29]. For both electrical and transmission microscopy measurements on the same sample, we fabricated Hall-bar type FGT devices on a 100-nm-thick Si₃N₄ membrane using soft mechanical exfoliation technique together with e-beam lithography and lift-off (see Methods and Supplementary Fig. S1 [30] for details). Figure 1b shows the cross-sectional view of high-resolution transmission electron microscopy (HRTEM) images of the device, where layered high-crystalline quality FGT is observed (Fig. 1b, inset). Note that FGT layer is sandwiched by two oxidized FGT (O-FGT) due to the sample fabrication under ambient condition, and 5 nm-thick Pt was deposited ex-situ as a capping material to prevent further oxidation (see Methods and Supplementary Fig. S2 [30] for details). The magnetic hysteresis behaviors of the FGT device were measured using the Hall resistance (R_{xy}) measurement, where external magnetic field was applied to out-of-plane direction at controlled temperatures ranging 100 K - 220 K (Fig. 1c). While the R_{xy} consists of a normal Hall resistance (R_N) and an anomalous Hall resistance (R_{AH}), FGT films exhibit a large value of R_{AH} in R_{xy}, which roughly scales with the magnetization (M) [7]. Therefore, the square hysteresis loops at 100 K in Fig. 1c corresponds to an out-of-plane magnetic anisotropy, which persists up to 200 K (T_C ~ 200 K). It is noteworthy that R_{xy}...
measurements yields two distinct slopes (sharp and slanted slopes) in temperature range, 100 K ≤ T ≤ 180 K, and the slanted area becomes more prominent as temperature increases. This area indicates the presence of multi-domain state, where the initially nucleated domains at sharp but incomplete switching propagate across the film, originating from the reduced magnetic anisotropy of FGT at higher temperature due to increased thermal fluctuations. Using this slanted area, we can drive the magnetization into multi-domain state at low temperatures and near zero magnetic fields, as shown in Fig. 1d. Red and blue curves indicate down-to-up and up-to-down switching at 120 K, respectively. For example, at a down-(up-)magnetization saturation state, increasing (decreasing) magnetic field just enough to generate multi-domain states and then subsequently reversing the field drives the overall magnetization into multi-domain states near zero magnetic field. This technique was employed to generate multi-domains during STXM, which require large moments and multi-domain states for high contrast observations.

Figure 2a shows the schematic of STXM experimental setup, where the temperature of cooling stage was controlled between 100 K ≤ T ≤ 300 K using liquid nitrogen (LN$_2$) and heat-exchanger. The scanning electron microscopy (SEM) image of measured FGT device with Hall-cross geometry and the electrical circuit diagram is also included in Fig. 2a (see Methods for details). The magnetization state of FGT device was imaged by probing the intensity of transmitted circularly-polarized X-ray at the Fe-edge ($L_3$ absorption edge), where X-ray magnetic circular dichroism (XMCD) provides contrasts corresponds to the out-of-plane magnetization. Figure 2b shows the magnetic domain configurations in the FGT device as a function of out-of-plane magnetic field, $B_z$, at 120 K, which confirms strong magnetic contrast observable in FGT from STXM measurements. Note that the alternative field-sweep procedure ($B_z = ±200$ mT → −60 mT → 0 mT) described in Fig. 1d was used to generate the initial magnetic configuration at zero field, $B_z = 0$ mT. The dark and bright contrasts in STXM images correspond to downward ($−M_z$) and upward ($+M_z$) out-of-plane magnetization direction of Fe atoms in FGT, respectively. With increasing out-of-plane field $B_z > 0$, the up domains expand while the down domains shrink into narrow domains, vanishing at the saturation field of $B_z = +80$ mT.

B. Dynamic generation and stabilization of SkX

Having established that multi-domain states can be readily stabilized and observed in FGT, we then examined the current-induced generation of magnetic skyrmions, as summarized in Fig. 3. In our previous study using conventional chiral ferromagnetic multi-layers, Pt/CoFeB/MgO, we demonstrated that the application of bipolar pulses could transform labyrinth domains with chiral domain walls into multiple skyrmions [31], and the recent study by Lemesh et al. (ref. [32]) unveiled the mechanism to be current-induced thermal transformation into skyrmions, because the energy barrier towards the global skyrmionic ground state decreases with increasing temperature. To utilize the same technique on the FGT device, we applied the burst of 100 bipolar pulses, where the pulse frequency of 1 MHz, the peak-to-peak voltage of $V_{pp} = 2.96$ V and the pulse width of 10 ns were used at $B_z = −40$ mT and 120 K. As shown in Fig. 3a, it is obvious that the bipolar pulse injection transformed the labyrinth random domain state into multiple circular domain state, where these circular domains turn out to be Néel-type chiral magnetic skyrmions in Fig. 4. It is noted that the labyrinth random domain state is maintained when the strong current pulses are applied at zero magnetic field. Thus, the spontaneous transition between the labyrinth random domain state to skyrmionic state is triggered by both the external magnetic fields and strong current pulses. We performed the same procedure at slightly lower temperature, 100 K, and the consistent transformation into multiple skyrmions is observed and the generated skyrmions remain stable at zero magnetic field, $B_z = 0$ mT (highlighted in a blue-boxed area in Fig. 3a). As was observed in ferromagnetic chiral multi-layers, the thermal excitation induced by the bipolar pulses may have opened a path towards global skyrmionics state [31,32]. We examined and observed the consistent domain transformation in another sample capped by graphite, as shown in Supplementary Fig. S3 [30]. This demonstration with graphite-capping is significant, as it excludes two possible contributions from Pt: i) the spin-orbit torques (SOTs) by transmitted spin current caused by the spin-Hall effect (SHE) in Pt [33] and ii) the DMI contribution from Pt/O-FGT interface. Additional Hall measurements presented in Supplementary Fig. S4 [30] also confirm the negligible influence from capping materials on the magnetic properties of studied FGT structure. Further analysis reveals that the average size of zero-field skyrmion is ∼ 123 nm at 120 K, and the size decreases down to ∼ 80 nm with increased density at 160 K (see Supplementary Fig. S5 for details [30], and references [61-63] therein).

At such disordered multi-skyrmion state at 100 K, we applied alternative positive and negative magnetic fields with increasing magnitude up to $B_z = ±80$ mT with the step of $B_z = ±10$ mT, as the application of static fields could annihilate pinned weak skyrmions and rearrange them driven by inter-skyrmion repulsive forces, leading to the stabilization of ordered skyrmion state [34,35]. Figure 3b shows the zero-field magnetic configuration after the field sweep, and surprisingly, the initial disordered magnetic skyrmions transformed into ordered hexagonal SkX. The inset of Fig. 3b presents the enlarged STXM images at a magnetic field, $B_z = −80$ mT, where the ordered SkX state is more clearly observable (few SkXs are highlighted with blue colors and white lines for guide). As shown in the inset of the enlarged image in Fig. 3b, the presence of six spots in
the fast-Fourier transform (FFT) image also supports the presence of the ordered SkX state in our sample. The symmetry of SkX also agrees with the symmetry observed in non-centrosymmetric B20-type chiral magnets [15,16]. After stabilizing the SkX state, we then plotted the experimental phase diagram of magnetic configurations in FGT, based on the real-space STXM measurements as summarized in Fig. 3c. We observed three magnetic configuration phases: i) SkX, ii) the co-existence of SkX and multi-domains, and iii) saturated ferromagnetic states, where the representative STXM images of each state are included in the right panel of Fig. 3c. It should be noted that, once generated, SkX in FGT can be stabilized at a wide
range of magnetic field and temperature. Moreover, SkX state remains stable at zero magnetic field. Together with the recent discovery of gate-tunable room-temperature magnetization in the same material [7], it might also be possible to harness and manipulate magnetic skyrmions and their lattice at room temperature and zero magnetic fields, which may constitute a major step towards room-temperature skyrmion applications based on vdW magnets.

C. Lorentz transmission electron microscopy (LTEM) study of SkX

To deeply understand magnetic configurations observed by STXM measurements, we first performed the LTEM measurement as summarized in Fig. 4 (see Methods for details [30], and references [36,53,54] therein). Note here that Fresnel-LTEM is useful to detect the in-plane components of Bloch-type spin spirals at defocused modes, whereas it cannot directly observe Néel-type magnetic configurations with zone-axis beam irradiation, due to the cancellation of magnetic inductions between electrons and symmetric in-plane magnetic moments with opposite directions projected by Néel-type spin textures [36–38]. However, when samples are tilted away from the zone-axis, the projected configurations of up- down magnetic domains should contribute to the LTEM contrasts at defocused modes, therefore, Néel-type magnetic configurations can be observed [35-38].

Figure 4a first shows in- and de-focus LTEM images of the FGT sample tilted about −20° along the x-axis at zero field and 160 K, where dark/bright contrasts are only visible in defocused images. Moreover, as shown in the red-boxed areas in the left and right images in Fig. 4a, under- and over-focus LTEM images exhibit the labyrinth domain structures with reserved domain wall contrasts, indicating a multi- domain state in the FGT flake at zero field [37–39]. To generate SkX, we then performed the field cooling (FC) of FGT with an oblique magnetic field of \( B = -40 \text{ mT} \) (the oblique angle is 20° to the zone-axis). Figure 4b shows LTEM images observed at 160 K. Noticeably, the FC generated quasi-static (metastable) Néel-type chiral SkX state in FGT crystal, which magnetic configurations as well as in-plane magnetization profiles agrees well with simulated LTEM results (Fig. 4c) (see Methods and Figs. S6 and S7 for details [30]). Considering that the oblique field applied during the LTEM measurements could have contributed to the in-plane alignment of magnetic moments within FGT domain walls, we have performed LTEM observations of SkX at zero field after the same FC process as described above, which confirmed the robustness of FC-driven static SkX (see Supplementary Fig. S7 [30]).

D. Current-driven motion of isolated skyrmions

To further highlight the potential of FGT-based 2D vdW heterostructures for skyrmion devices, we next demonstrate the current-driven motion of skyrmions in this material, as summarized in Fig. 5. Figure 5a shows a schematic image of the FGT track and electric contacts fabricated on Si\(_3\)N\(_4\) membrane for STXM measurements. Note that a thin h-BN vdW flake is used as a capping material on FGT, where the FGT layer is sandwiched by two naturally O-FGT as was also shown in Fig. 1b. In this experiment, we first generated initial few-skyrmion-state (as shown in the first image of Fig. 5b) by applying external magnetic field to the multi-
contrast profiles across a single skyrmion as shown in b. Note that the simulated profiles were obtained for a 100 nm-size Néel-type skyrmion.

skyrmion state acquired by the current-driven skyrmion generation process described in Fig. 3, while an oblique magnetic field of $B = -50$ mT (the oblique angle is 30° to the zone-axis) was applied at $T = 100$ K. In Fig. 5b, each image was obtained after injecting 5 current pulses with $J_e = 1.4 \times 10^{11}$ A/m² and $t_{pulse} = 50$ ns. The current was applied along the $+x$ direction, opposite to the electron flow along $-x$ direction as schematically indicated in each image.

It is first noteworthy that skyrmions move upon the application of current pulses, and the propagation direction is along the electron-flow direction (against current flow), where this directionality indicates that skyrmions are driven by spin-transfer torques (STTs) arising within the FGT. This is also expected from the HRTEM image shown in Fig. 5a, exhibiting no possible interface of FGT that could provide vertical spin current by e.g. SHE. As shown in Fig. 5c, the average skyrmion velocity was measured to be ~1 m/s at a current density $J_e = 1.4 \times 10^{11}$ A/m², below which no skyrmion motion is observed. The current-driven motion of skyrmion shows the potential of using skyrmions in FGT for functional device applications, such as the racetrack-type memory [20], where skyrmions act as moveable information carriers.

It should also be noted that, although we initially observed three stabilized skyrmions (Sk1-3), only one skyrmion (Sk2) remains stable and propagates along the track during the their motion. We speculate such non-ideality may come from the interplay between various magnetic parameters in FGT that sharply changes with temperature, which then alters skyrmion stability as was experimentally navigated in Fig. 3c. However, we believe that further experimental studies of skyrmion motion in FGT-based 2D heterostructures using more efficient torques, e.g. SOTs, arising from some known 2D materials with very large charge-to-spin conversion efficiency, e.g. WTe₂ or NbSe₂, could substantially improve their electrical controllability and current-velocity relation that could exceed conventional metallic systems [40–43].

E. First principle calculation on Dzyaloshinskii-Moriya interaction (DMI) from O-FGT

With these experimental demonstrations of chiral skyrmions, their SkX state and their current-driven motion in the FGT-based heterostructures, let us now discuss physical origins of DMI in vdW FGT crystals. We first examined the possible DMI sources from the FGT crystal symmetry. As discussed earlier, a monolayer of FGT contains three Fe sublayers (i.e., a 2D Fe II and Ge sublayer between two 2D Fe III sublayer), forming a hexagonal structure that is sandwiched between two Te layers. The whole FGT monolayer structure has the non-centrosymmetric point group of $D_{3h}$ [28,44] and thus in principle, shows no bulk DMI. Indeed, although some locally broken inversion symmetry of sublayers in FGT could result in the DMI that stabilizes Néel-type skyrmions, all possible DMI contributions in the whole FGT monolayer structure cancel each other as discussed and summarized in Supplementary Fig. S8 and Supplementary Table S1 [30]. For example, similar to the case of 2D hexagonal boron nitride structure with buckling [45], the top Fe III sublayer and neighboring Te layer form a lattice of $C_3v$ point group with broken inversion symmetry, the interfacial DMI could be induced at the top Fe III sublayer via the superexchange along the Fe III-Te-F e III path. However, due to the reflection symmetry of the system, the DMI contributions induced at
the top and bottom FeIII sublayers are cancelled with each other and the net DMI in the whole FGT structure vanishes.

In order to elucidate the possible origin of DMI at atomic level, we performed first principles calculations employing the approach used for multi-layers comprising magnetic and heavy metals [46], oxides [47] and graphene [48] (see Methods for details [30], and references [55-60] therein). We first verified that the DMI for symmetric FGT structure indeed vanishes as discussed above. For FGT crystal monolayer the calculated DMI, arising at both Fe/Te interfaces is of almost equal magnitude with opposite sign yielding negligible DMI as expected from aforementioned crystal symmetry analysis. This is in agreement with SOC energy difference associated with the total DMI, $\Delta E_{\text{SOC}}$, for the same FGT crystal monolayer presented in Fig. S9b [30]. We would also like to note that this result of non-existing interfacial DMI in FGT bulk crystal has also been reported recently by Laref et al. [49], opposing to another work by Wang et al. [24] that estimates some finite DMI within FGT.

We next investigated other possible mechanisms of induced DMI by examining global and local atomic distributions along FGT crystal and its interfaces. Figure 6a shows atomic concentrations across the sample acquired using the quantitative high-angle annular dark field detector (HAADF) installed in scanning transmission electron microscopy (STEM) (see Supplementary Fig. S2 [30] for elemental mapping images). One can note first that the concentration of each atom along the thickness of sample within in the pure FGT crystal region is symmetric and homogeneous, implying that the DMI owing to asymmetric distribution of elemental content in bulk material, as presented in ref. [50], can be excluded in this case. However, it is noteworthy that there exists significant atomic concentration fluctuation at two FGT/O-FGT interfaces. In particular, the concentration of Te atom at both interfaces rapidly decreases and vanishes upon oxidation, while Fe and Ge concentrations only fluctuate and recover their original values near the largest oxidation areas (oxygen peaks). Figure 6b shows the relative atomic concentration distribution between Te and O atoms, where their sum and difference are plotted. It becomes clearer that, while their total concentration (Te+O) fluctuates within 10~15%, their concentration difference (Te-O) rapidly decreases from the initial bulk value of Te, ~ 30%, to its negative value, ~ -30%, around oxygen concentration peaks. This distribution variation between Te and O elemental contents strongly implies that Te atoms are likely substituted by O atoms, forming Fe$_3$GeTe$_{2-x}$O$_x$ over few nanometers of oxidized interfacial regions. Furthermore, one cannot exclude oxygen addition scenario at the interfaces as well. Therefore, we performed systematic calculations of microscopic and micromagnetic DMI.
parameters \((d\text{ and } D)\), for both O-substitution and O-addition scenarios using single crystal monolayer and bulk FGT structures (Figs. 6c-j). In both scenarios, we found that the DMI is anisotropic in plane yielding \(d_{[100]}\neq d_{[110]}\) (Figs. 6c-i). Of note, similar behavior was also reported for out-of-plane magnetized bcc Au/Co/W structures [51]. For O-substitution case, we find that the single crystal monolayer DMI is nonmonotonic as a function of oxygen concentration, being weakly anticlockwise (resp. strongly clockwise) for low (resp. high) concentrations (Figs. 6d-f).

As for the case of O-addition scenario, the DMI strength monotonically increases as a function of oxygen concentration, although \(d_{[100]}\) and \(d_{[110]}\) configurations give opposite DMI chirality (Fig. 6g-i). Regarding the DMI in the bulk O-substituted FGT structures, very importantly, we found additional DMI contributions arising from the proximity of pure FGT cell with the oxidized layer O-FGT. For instance, it follows from \(\Delta E_{SOC}\) distribution shown in Fig. 6j, that O-FGT and FGT parts of this bulk structure provide clockwise [100] DMIs with -0.6 meV and -0.8 meV contributions, respectively, resulting in total value of -1.4 meV indicated by black solid square in Fig. 6f. The difference of about -1 meV between the total DMI values for the bulk O-FGT/FGT and O-FGT fully oxidized single crystal monolayer (open square in Fig. 6f), clearly indicates the large clockwise DMI contribution associated with the bulk FGT part in this structure. Similar conclusions can be deduced for [110] structure. As for O-addition scenario, these net FGT bulk contributions in O-FGT/FGT resulting from oxygen gradient within the structure are significantly smaller (Fig. 6i).

Using these theoretical findings, we can now analyze the resulting DMI in our samples supposing that these oxidation scenarios occur within interfacial areas with transient Te-O concentration represented by shaded areas in Fig. 6b, with top (5.9 nm) oxidized region being thicker compared to the bottom one (3.3 nm). These relatively thick regions with variable oxidation rate within them suggest that the DMI is not “localized” at narrow interfaces between atomic layers. Instead, the whole thickness regime with a finite oxidation gradient serves as DMI-enhancing layer across few nanometers, which works together with Heisenberg exchange, dipolar energy and anisotropy, leading to the formation of chiral magnetic skyrmions and their lattices observed here. Although two O-FGT/FGT interfaces are symmetically present in our FGT sample and therefore may counteract, the magnitudes of DMI in these interfaces may be very different due to largely asymmetric oxidation profile and aforementioned scenarios (substitution and addition). In fact, even in case of only substitution scenario present, the overall net clockwise DMI will be present due to oxidation region asymmetry. Moreover, both O and Te interfacial gradients favors O-substitution scenario which gives rise to clockwise DMI provided by FGT adjacent layers.

To further corroborate our ab-initio study, we performed magnetic imaging of another FGT-based heterostructure without any O-FGT interfaces, as shown in Fig. S10 [30]. In this experiment, we used DPCM by configuring the magnetic structure in low-magnification scanning mode (STEM), which enables the direct measurement of the in-plane magnetic components in focus to avoid feature blurring via defocus inherent in LTEM imaging obtained at defocused mode [52]. The DPCM measurement and analysis present that the observed magnetic textures are Bloch-type, in good agreement with previous LTEM results observed in a FGT flake without oxidized interfaces [23]. This is significant, as it highlights that we can now manipulate the chiral state of magnetic texture (i.e. Neel-type vs. Bloch-type) in vdW heterostructures by employing different fabrication processes. Moreover, following the physical insights revealed by our work, we believe that future studies could utilize 2D heterostructures consist of non-oxidized FGT and other oxide vdW materials (e.g. FGT/V_{2}O_{5}) for engineering interfacial DMI in a more controllable way.

Nevertheless, we believe further systematic experimental studies probing the dependence of spin textures on the total FGT thickness, and/or the internal magnetization profile of skyrmions from top to bottom layers in FGT considering the role of van der Waals interactions could shed light into more precise tailoring of DMI and resulting magnetic textures in FGT crystal and heterostructures.

### III. CONCLUSIONS

In summary, we observed Néel-type chiral magnetic skyrmions and their lattice phase stabilization in a vdW ferromagnet FGT using high resolution magnetic microscopy. We examined the stability of SkX in FGT over a wide range of temperatures and magnetic fields, including its zero-field manifestation. We also demonstrated current-driven motion of individual skyrmions in FGT, highlighting its potential for device applications. We performed symmetry analysis and first principles calculations to unveil the origins of the emergent Néel-type spin textures, namely DMI at the oxidized interfaces of FGT, which also demonstrates the controllability of chiral states in vdW heterostructures by process and/or interfacial material engineering. The possibility to achieve and electrically manipulate magnetic skyrmions in vdW magnets marks a significant advance in vdW magnet-based spintronics. Our results can support a further understanding of the field-driven and current-driven dynamics of skyrmions in 2D vdW materials and provide guidelines for the design of magnetic devices based on 2D materials. Along with the large potential of skyrmions for future spintronic devices to store, process, and transmit data with extremely low power.
cost, this work will pave a route towards vdW magnet-based topological magnetism and skyrmion-electronics.

Part of this work was performed at the MAXYMUS endstation at Berlin Electron Storage Ring Society for Synchrotron Radiation II (BESSYII). We thank HZB for the allocation of neutron/synchrotron radiation beamtime. Part of this work was also performed at the PoLLux (X07DA) endstation of the Swiss Light Source, Paul Scherrer Institut (PSI), Villigen, Switzerland. We thank PSI for the allocation of synchrotron radiation beamtime.

Author contributions

S.W. designed and conceived the study. T.-E.P. prepared films, fabricated devices and performed device characterizations with the support from S.J.K. K.M.S., K.K. and Y.D.K.. T.-E.P, K.M.S., K.K., M.W., S.F., J.R. and S.W. performed STXM experiments at BESSY II in Berlin, Germany and at Swiss Light Source in Villigen, Switzerland. L.P. and X.Z.Y. performed Lorentz-TEM experiments and analyzed the data. F.S.Y. performed DPCM and Lorentz-TEM experiments on non-oxidized FGT and analyzed the data. J.L., A.H., A.F., M.C. and H.Y. performed the ab initio calculations on DMI in FGT crystal, and analyzed the results. X.Z. performed symmetry analysis on DMI in FGT crystal. T.-E.P. drafted and L. P., X.Z., Z.X.Y., F.S.Y. and S.W. revised the manuscript and all authors reviewed the manuscript.
