In this paper, we study transport properties of non-equilibrium systems under the application of light in many-terminal measurements, using the Floquet picture. We propose and demonstrate that the quantum transport properties can be controlled in materials such as graphene and topological insulators, via the application of light. Remarkably, under the application of off-resonant light, topological transport properties can be induced; these systems exhibit quantum Hall effects in the absence of a magnetic field with a near quantization of the Hall conductance, realizing so-called quantum Hall systems without Landau levels first proposed by Haldane.

I. INTRODUCTION

Application of light is a powerful method to change material properties. For example, light can induce currents through mechanisms such as photovoltaic effect\textsuperscript{1}, photothermoelectric effect\textsuperscript{2}, and photo-drag effects\textsuperscript{3}. Moreover, light can change the response of materials and induce insulator to metal transitions\textsuperscript{4} or change the characteristics of $p\rightarrow n$ junctions\textsuperscript{5}.

In recent years, there has been tremendous developments and interests in the induction of quantum phases through light applications. For example, experiments have demonstrated that superconductivity can be induced through infrared pulses in high-temperature cuprate superconductors\textsuperscript{6}. Inductions of quantum phases are inherently non-equilibrium phenomena, and thus their understanding is quite challenging. Even some basic questions such as the physical signatures of the induced phases and how such phases can be stabilized in a steady state do not have answers yet. Many of quantum phases manifest themselves through transport, and therefore, understanding of transport properties in non-equilibrium, open systems is crucial for experimental verifications of such induction of quantum phases under the application of light. In this paper, we develop a general formalism for studying non-equilibrium transport under the application of light, and, using the formalism, address the possibilities of the induction of topological properties through light.

Motivated by recent rapid development of the understanding in topological phases, the possibility of inducing topological phases such as integer quantum Hall phase and topological insulators through light has been theoretically explored by many different groups\textsuperscript{9-11}. Generally speaking, the application of light on electron systems has two important physical effects; 1. photodressing of band structures through the mixing of different bands 2. redistribution of electron occupation numbers through the absorptions/emissions of photons leading to non-equilibrium distributions. Previous works proposed optical induction of band structures with topological properties\textsuperscript{9-11}, and thus have mostly focused on the analysis of the first effect. On the other hand, most of these works do not address the question of the second effect, the redistribution of electrons in the band structure, and thus its physics is yet poorly understood. Topological properties only appear when certain bands are fully filled, and it is not clear how this band occupation can be achieved and topological properties survive when the system is strongly driven out of equilibrium by the application of light.

In order to answer these questions, we study the physical consequence of the application of light through DC many-terminal transport measurements as in Fig. 1. The coupling of the driven systems with leads, that are in return coupled with equilibrium reservoirs, plays the crucial role to determine the occupations of electrons. Using the formalism for transport properties in periodically
driven systems developed by various groups\textsuperscript{12}, here we study topological transport phenomena in materials such as graphene and three dimensional topological insulators. First of all, we show that non-equilibrium transport properties cannot generally be captured by the photon-dressed, effective band structures. In particular, in addition to the usual transport through such static effective band structures, there are contributions from photon-assisted electron conductions. Thus, the induction of topologically non-trivial band structures does not immediately imply the topological properties of the non-equilibrium systems.

On the other hand, the regime exists in which topological band structures can manifest themselves; we explicitly demonstrate that for off-resonant light where electrons cannot directly absorb photons, the transport properties of the non-equilibrium systems attached to the leads are well approximated by the transport properties of the system described by the static effective Hamiltonian that incorporates the virtual photon absorption processes. In particular, the occupations of the electrons under this situation are close to the filling of the photon-dressed bands. As examples, we show that the transport properties under the application of off-resonant light is given by the photon-dressed Hamiltonian corresponding to a quantum Hall insulator without Landau levels\textsuperscript{2} in the case of graphene, and to a gapped insulator with anomalous quantum Hall effects and magneto-electric response described by axion electrodynamics\textsuperscript{8} at the surfaces of three dimensional topological insulators. In these systems, the measurements in six-terminal configurations in Fig. 1 lead to the near quantization of Hall conductance. Thus, the application of off-resonant circularly polarized light leads to an intriguing "Hall" effects without applying a static magnetic field.

This paper is organized as follows. In Section II, we describe the summary of the results, focusing on the analysis of graphene and three dimensional topological insulators under the application of off-resonant light. Here we provide the physical and intuitive explanations of the phenomenon of light-induced quantum Hall effects and refer to later sections for many important details. In Section III, we develop the formalism for studying the non-equilibrium transport properties under periodical drives in many-terminal measurements. Our formalism is based on the extension of the multi-probe B"{u}ttiker-Landauer formula\textsuperscript{14} to periodically driven systems, a "Floquet Landauer formula." We provide two distinct ways to calculate the transmission amplitudes in the driven systems. First method expresses the results in terms of the Floquet states and it illuminates the physical origin of the photon-assisted transport. Second method takes advantage of "Floquet Dyson's equation" to give an elegant solution which is more convenient for numerical solutions\textsuperscript{17}. By taking the off-resonant limit of these solutions, the equivalence of transport properties under the application of light and those with effective photon-dressed Hamiltonian is established.

Most of the analysis in this paper assumes the absence of interactions among electrons as well as electron-phonon interactions. We argue in Section IV that, in the case of graphene and topological insulators under the off-resonant light, the results given in Section II are robust against these interaction effects at low temperatures. While the measurements of transport properties require the attachment of leads, the probe of the effective gap induced by light is plausible even in an isolated system. We propose in Section V such measurements through the adiabatic preparation of non-equilibrium systems combined with the transmission of probe laser with small frequencies. The essential ingredients in the arguments of Section IV and Section V are the extensions of adiabatic theorem and Fermi golden rule to periodically driven systems and Floquet states, dubbed as "Floquet adiabatic theorem" and "Floquet Fermi golden rule." We give the detailed proof of these important statements in the Appendix. In Section VI, we conclude with possible extensions of this work.

II. SUMMARY OF RESULTS

A. Graphene effective Hamiltonian

Here we consider graphene as an example of semimetals and study the change in the transport properties under the application of light. We model graphene by a hexagonal tight-binding model with two \( \pi \)-bands, where we first neglect the electron-electron as well as electron-phonon interactions. In Section IV, we discuss the effects of these interactions and argue that they do not change the qualitative results of the analysis. We consider the application of circularly polarized light perpendicular to the plane of graphene. For concreteness, here we represent the rotating electric field due to light as a time-dependent vector potential \( \mathbf{A}(t) = A(\pm \sin(\Omega t), \cos(\Omega t)) \) with \( \mathbf{E}(t) = \partial \mathbf{A}(t)/\partial t \), where \( \Omega \) is the frequency of light. Plus sign is for right circulation of light and minus sign for left circulation. The light intensity is characterized by the dimensionless number \( A = e A_0/\hbar \) where \( e \) is the electron charge and \( A_0 \approx 2.46 \AA \) is the lattice constant of graphene. For intensity of lasers and pulses available in the frequency regime of our interests \( \sim 1000 \text{THz} \), \( A \) is typically less than 1. In this gauge, electrons accumulate phases as they hop in the lattice:

\[
H(t) = -J \sum_{<ij>,s} e^{i A_{ij}(t)_{c_{i,s}^\dagger c_{j,s}}},
\]

where \( A_{ij}(t) = e/\hbar (r_j - r_i) \cdot \mathbf{A}(t) \) with \( r_i \) being the coordinates of the lattice site \( i \), \( J \) is the hopping amplitude of electrons, and \( s = \uparrow, \downarrow \) are spins of electrons. For simplicity, we only consider the orbital effect of electromagnetic fields on electrons, and disregard the small Zeeman effect. The inclusion of the Zeeman effect is straightforward. In this limit, spins trivially double the Hilbert space and thus we suppress the spin indices in the following.
When the light frequency is off-resonant for any electron transitions, light does not directly excite electrons and instead, effectively modifies the electron band structures through virtual photon absorption processes. Such off-resonant condition is satisfied for the frequency $\Omega \gg J$ in our model with $\pi$-bands. More general case of on-resonant light can be analyzed through the formalism developed in later section Section III. The influence of such off-resonant light is captured in the static effective Hamiltonian $H_{\text{eff}}$ defined through the evolution operator $U$ of the system after one period $T = 2\pi/\Omega$ as

$$H_{\text{eff}} = \frac{i}{T} \log (U)$$

where $U = \mathcal{T} \exp \left(-i \int_0^T H(t) dt \right)$ and $\mathcal{T}$ is the time-ordering operator. Intuitively, $H_{\text{eff}}$ describes the dynamics of the system on time scales much longer than $T$. In the limit of $A^2 \ll 1$, $H_{\text{eff}}$ is particularly simple near the Dirac points:

$$H_{\text{eff}} \approx H_0 + \frac{[H_{-1}, H_1]}{\Omega} + O(A^4)$$

$$\approx v_G (\sigma_y k_x - \sigma_x k_y \tau_z) \pm \frac{\sqrt{2} A^2}{\Omega} \sigma_z \tau_z + O(A^4)$$

(for infinite system),

where $H_n$ is the discrete Fourier component of Hamiltonian, i.e. $H_n = \frac{1}{T} \int_0^T H(t) e^{i\Omega n t} dt$. In the second line, $v_G = 3J/2$ is the velocity of Dirac electrons, $k_x$ and $k_y$ are momenta measured from the Dirac points, $\sigma_i$ and $\tau_z$ are Pauli matrices representing sublattice and valley degrees of freedom, respectively.

The modification of the Hamiltonian with respect to the static component $H_0$ is the second term in Eq. (3). This term can be easily understood as the sum of second order processes as illustrated in Fig. 2 a); one where electron absorbs a photon and then emits a photon $H_{-1} \frac{1}{\omega - \Omega} H_1$ where $\omega$ is the energy of the original electron; another where electrons first emits a photon and then absorbs a photon, which leads to $H_{-1} \frac{1}{\omega - \Omega} H_1$. By summing these two contributions, we obtain the correction due to the second order process, given in the second term of Eq. (3). In the second line, the plus sign is for right circulation of light polarization and the minus sign is for left circulation. For details of derivations, see Section III. We note that the expression of the effective Hamiltonian in Eq. (3) is only valid in the gauge in which light is represented as time-dependent vector potential, and the effective Hamiltonian has different forms for other gauge such as the one in which light represented as time-dependent electric fields. The effect of virtual photon absorptions at the degenerate Dirac points is to open a gap with magnitude $\Delta = \frac{2v_G A^2}{T}$. In Fig. 3, we illustrate the opening of the gap near one of the Dirac points upon the application of light for both infinite and finite systems. This Hamiltonian $H_{\text{eff}}$ corresponds to a quantum Hall insulator, where each band is characterized by non-zero Chern number $^7, ^{26}$.
We show above (also see Section III B 2) that the virtual photon absorption and emission process represented by the second term of Eq. (3) induces a gap at the Dirac point and leads to a non-zero Chern number. Such photon-dressing, which was neglected in the study of Ref. [18], has dramatic effects at the degenerate Dirac point and leads to a non-zero Chern number. 

There are a few different ways to probe the gap $\Delta$ in the effective Hamiltonian. For example, the gap opening of Floquet states for a single spin is illustrated in the upper figure. In this case, the Dirac points are at $k_x = 0$. $H_{\text{eff}}$ shows the existence of gapless chiral edge states for each spin originating from non-zero Chern numbers of the bands, that are colored as blue and green, corresponding to the edge state in the upper and lower edge, respectively. The propagation of chiral edge states for a single spin is illustrated in the upper figure.

B. Floquet-Landauer formalism and Hall current

One of the central results of this paper is the demonstration that measurements of DC current of the non-equilibrium system under the application of off-resonant light is determined by the static, photon-dressed Hamiltonian $H_{\text{eff}}$. To this end, we consider the many-terminal measurements of DC current under the application of light as in Fig. 1.14. The non-equilibrium transport properties of mesoscopic, periodically driven systems in this configuration have been studied previously, using Floquet theory combined with the Keldysh formalism. We express the general result obtained in these works as the extension of the multi-probe Büttiker-Landauer formula to periodically driven systems, a "Floquet Landauer formula"; 

$$J_{\alpha}^{\text{dc}} = J_{\alpha}^{\text{pump}} + J_{\alpha}^{\text{res}}$$

$$J_{\alpha}^{\text{res}} = \sum_{\beta} \left( \sum_{n} T_{\alpha\beta}(n) \right) (\mu_{\beta} - \mu_{\alpha}) \quad (5)$$

Here $J_{\alpha}^{\text{dc}}$ is the DC component of the current at lead $\alpha$, $J_{\alpha}^{\text{pump}} = \frac{j_0}{T} \int_{0}^{T} J_0(t) dt$. Here we assumed that the reservoirs are at zero temperature, and their chemical potentials $\{\mu_{\alpha}\}$ are near the Dirac points, i.e., $\mu_{\alpha} \approx 0$. The DC current of a periodically driven system in Eq. (4) consists of two physically distinct contributions: the pump current $J_{\alpha}^{\text{pump}}$, which can be present even when all the reservoirs have the same chemical potential $\mu_{\alpha}$ and the response current, $J_{\alpha}^{\text{res}}$, which arises from the response of the driven system to the chemical potential differences of the reservoirs. For the application of light we consider in this paper, the pump current $J_{\alpha}^{\text{pump}}$ is zero for inversion symmetric geometries, so we focus on the properties of the response current $J_{\alpha}^{\text{res}}$ in the following. The transmission coefficients $T_{\alpha\beta}(n)$ in Eq. (5) represent the transmission of electrons with energy $\mu_{\beta} \approx 0$ from lead $\beta$ to $\alpha$ during which electrons absorb (emit) $n$ photons as illustrated in Fig. 4.

Thus, the response conduction in the presence of periodic drive can be seen as an extension of the static conduction, where the transmission can now happen with the absorptions/emissions of photons. We note that the expression of DC current in Eq. (5) is valid for arbitrary strength and frequency of the

---

FIG. 3: a) The spectrum of graphene for a single spin near one of the Dirac points for an infinite system. Here we plot the energy spectrum of a static system corresponding to $A = 0$ (upper figure) and the spectrum of $H_{\text{eff}}$ for the system under the application of light with light intensity $A = 0.3$ (lower figure). A finite gap $\Delta$ opens at the Dirac point. b) The spectrum of $H_{\text{eff}}$ for a single spin near one of the Dirac points for infinite system in $x$ direction and 150 sites in $y$ direction for $A = 0.3$. The frequency of light is chosen to be off-resonant with $\Omega = 7.5 J$. Here we chose the armchair edges, and in this case, the Dirac points are at $k_x = 0$. $H_{\text{eff}}$ shows the existence of gapless chiral edge states for each spin originating from non-zero Chern numbers of the bands, that are colored as blue and green, corresponding to the edge state in the upper and lower edge, respectively. The propagation of chiral edge states for a single spin is illustrated in the upper figure.

FIG. 4: Illustration of the response conduction current in Floquet Landauer formula given in Eq. (5). The transmission of the electrons can now happen with $n$ photon absorptions/emissions. The total conductance is simply given by the sum of these contributions for each $n$. 

[18], we show above (also see Section III B 2) that the virtual photon absorption and emission process represented by the second term of Eq. (3) induces a gap at the Dirac point and leads to a non-zero Chern number. Such photon-dressing, which was neglected in the study of Ref. [18], has dramatic effects at the degenerate Dirac points and should be taken into account.

There are a few different ways to probe the gap $\Delta$ in the effective Hamiltonian. For example, the gap opening might be confirmed through the observation of the transmission of low frequency probe lasers. In Section V, we propose the possibility to probe this dynamically opened gap in an isolated system through adiabatic preparation of Floquet states. The main focus of this paper, however, is the study of the manifestations of the gapped Hamiltonian $H_{\text{eff}}$ in many-terminal transport measurements depicted in Fig. 1, which we now describe.
drives. The transmission probabilities $T_{\alpha\beta}(n)$ can be efficiently computed by dressing the propagators with photon absorptions/emissions\footnote{\cite{17}}, and will be described in Section III. We emphasize that the response current is generally the sum of the contributions from photon absorption/emission processes \(\text{(see Eq. (5))}\) and thus its transport property cannot be described by any static Hamiltonians. The off-resonant case described below is an exceptionally simple case in this respect.

We employ this Floquet-Landauer formalism to study the off-resonant, large frequency regime \(J \ll \Omega\) with weak intensity of light, \(i.e., A^2 \ll 1\). In this regime, absorptions or emissions of photons are suppressed by \(A^2\), and the transmission coefficients \(T_{\alpha\beta}(n)\) with \(n \neq 0\) is small and of the order of \(O(A^2)\). On the other hand, the zero-photon absorption/emission transmission coefficient \(T_{\alpha\beta}(0)\) is modified due to virtual photon processes. Such modifications are included in \(H_{\text{eff}}\) and the transmission probability is given by \(T_{\alpha\beta}(0) = T_{\alpha\beta}^{\text{eff}} + O(A^2)\), where \(T_{\alpha\beta}^{\text{eff}}\) is the transmission probability of the static system described by \(H_{\text{eff}}\). These results will be rigorously established in Section III.

This correspondence demonstrates, under our assumptions, that graphene under the application of off-resonant light behaves as an insulator with gap \(\Delta = \frac{2e^2}{h}\) with Hall conductance quantized at \(2e^2/h\) with possible corrections up to the order of \(O(A^2)\). Here the factor of 2 comes from spin degrees of freedom. While we established the results in the perturbation theory on \(A\), it is possible to analytically confirm the insulating behavior for all orders in \(A\) for weak contact couplings with leads\(\text{(see Section III)}\). We emphasize that although the effective Hamiltonian is perturbative in \(A\), the Hall conductance at zero temperature is non-perturbative: an infinitesimal gap \(\Delta\) is sufficient to yield a topological band with non-zero Chern number.

A distinct feature of this light-induced Hall effect above is that the Hall conductance switches its sign under the change of circulations of light polarization. This can be easily checked for the geometry of the system which is symmetric under \(x \rightarrow -x\), under which the circulation of light reverses. Such reversal of Hall current can be used in the experiments to distinguish this light-polarization dependent current from light-polarization independent current, which could originate from mechanisms we did not consider in this paper.

We briefly describe the requirements to observe the proposed phenomena with off-resonant light in graphene. The band width of graphene in the \(\pi\) orbital is given by \(6J\) where \(J \approx 2.4\text{eV}\), placing the required frequency of off-resonant light to be soft x-ray regime with \(\Omega = 3500\text{THz}\). For this frequency of light, the gap of the system \(\Delta\) can reach \(\Delta \approx 300\text{K}\) for the strong light intensity \(I \approx 3\times10^{12}\text{W/cm}^2\text{\cite{219}}\) which gives \(A \approx 0.09\), where we expect the Hall conductance to be quantized with possible correction of 1\% of \(2e^2/h\). In reality, even such high frequency of light is expected to be absorbed in graphene. Such direct electron excitations lead to reconfiguration of electron occupation numbers, which modifies the Hall conductance from its quantized values.

C. Three dimensional topological insulators

The analysis of graphene above can be directly extended to three dimensional topological insulators such as Bi\(_2\)Se\(_3\). The low energy description of electrons on surfaces of Bi\(_2\)Se\(_3\) is given by two dimensional Dirac fermions\footnote{\cite{20}}, and is described by the Hamiltonian \(H_{\text{surf}} = v_{\text{TI}}(k_x\sigma_y - k_y\sigma_x)\) where \(v_{\text{TI}}\) is the velocity of the Dirac fermion, and \(\sigma_i\) are Pauli matrices corresponding to two bands near the Dirac point. As before, we assume the application of weak, off-resonant, circularly polarized light. The orbital effect of the light is taken into account through the replacement \(k \rightarrow k - A(t)\). At the Dirac cone, the virtual photon process again opens a gap and the effective Hamiltonian is \(\text{(see Eq. (3))}\)

\[ H_{\text{eff}} = v_{\text{TI}}(k_x\sigma_y - k_y\sigma_x) \pm \frac{A^2 v_{\text{TI}}^2}{\Omega} \sigma_z \]  \hspace{1cm} (6)

where \(\pm\) corresponds to the gap due to right(left) circularly polarized light. The consequences of the gap coming from the third term in Eq. (6) are extensively investigated in Ref \[\cite{8,21}\]. Just as in the case of graphene, the induced insulator is topologically non-trivial, and expected to result in anomalous quantum Hall effect with Hall conductance \(\pm \frac{e^2}{2h}\) with possible corrections up to the order of \(O(A^2)\). Here we propose to probe the unique magneto-electric response of the gapped topological insulator through pump-probe type measurements, where circularly polarized light is used to open a gap at the Dirac point and linearly polarized light with small frequency within the gap is used to probe the Faraday/Kerr rotations\footnote{\cite{22}}, as illustrated in Fig. 5 a) \(\text{(also see Section V)}\). Unlike other schemes proposed previously with ferromagnetic layers, here the Faraday/Kerr rotations can only result from the topological insulators and they give unambiguous signature of magneto-electric effects. In a similar fashion, the existence of magnetic monopoles can be probed by placing an electric charge near the surface of the topological insulator in the presence of circularly polarized light \(\text{(see Fig. 5 b))}\).

D. Discussion

In the analysis of graphene and topological insulators above, we assumed the off-resonance of light for entire bands, but the gap in the effective Hamiltonian opens whenever the light is off-resonant near the Dirac points, which requires much less stringent condition on the light frequency. However when inter-band electronic transitions occur due to photon absorptions, subsequent relaxation processes are expected to change the electron occupation numbers in the steady state, and modify Hall conductance away from quantized values. Thus in the case of
on-resonant light, the system is expected to display non-quantized Hall effects without magnetic fields. Moreover, as we show in Section III, the application of on-resonant light leads to the photo-assisted conductance and the resulting non-equilibrium transport property can no longer simply be described by the static effective Hamiltonian. The transport under the on-resonant light contains rich physics in itself, and it will be studied in the future works. On the other hand, it is possible to achieve the off-resonance with small frequency of light in, for example, the gapped systems such as Boron-Nitride by applying the sub-gap frequency of light. Many of these possible extensions can be studied through the formalism developed in the following sections. The understanding and formalism obtained in this paper is likely to guide future searches for the optimal systems to study photo-driven quantum Hall effects without magnetic field.

III. NON-EQUILIBRIUM TRANSPORT: FORMALISM

A. Floquet Landauer formula

In this paper, we study the transport properties of systems under the application light in the Landauer-type configuration, where the systems are attached to the leads as in Fig. 1. Previous works\textsuperscript{12} obtained the DC current in periodically driven systems in terms of the Floquet Green’s functions $\hat{G}(\omega, n)$ which represent the Fourier transform of retarded Green’s function, and is a propagator with frequency $\omega$ which absorbs (emits) $n$ photons. Here we express the general results in physically transparent fashion;

$$J_{\alpha}^{\text{dc}} = J_{\alpha}^{\text{pump}} + J_{\alpha}^{\text{res}}$$

$$J_{\alpha}^{\text{pump}} = \sum_{n} \sum_{\beta} \int \frac{d\omega}{2\pi} T_{\alpha,\beta}(n, \omega)(f_{\alpha}(\omega) - f_{\alpha}(\omega + n\Omega))$$

$$J_{\alpha}^{\text{res}} = \sum_{n} \sum_{\beta} \int \frac{d\omega}{2\pi} T_{\alpha,\beta}(n, \omega)(f_{\beta}(\omega) - f_{\alpha}(\omega))$$

where $f_{\alpha}$ are the sites in graphene that are connected with leads $\alpha$, and $\Gamma_{\alpha}(\omega)$ represents the coupling strength with leads $\Gamma_{\alpha}(\omega) = t_{\alpha}^2 \rho_{\alpha}(\omega)$ where $t_{\alpha}$ is the hopping strength from graphene to lead $\alpha$ and $\rho_{\alpha}(\omega)$ is the density of states in the lead $\alpha$ at energy $\omega$. Also, $f_{\alpha}(\omega)$ is the Fermi function at lead $\alpha$, $f_{\alpha}(\omega) = \frac{1}{\exp(\frac{\omega - \mu_{\alpha}}{k_B T_{\alpha}}) + 1}$ where $\beta_{\alpha} = 1/k_B T_{\alpha}$ is the inverse temperature and $\mu_{\alpha}$ is the chemical potential of the reservoir connected to lead $\alpha$. If we take the zero temperature limit and assume that differences of chemical potentials at each lead are small, the expression in Eq. (7) is reduced to the simpler Floquet Landauer formula given in Eq. (5).

The calculation of conductance given by $J_{\alpha}^{\text{res}}$ reduces to the calculation of Floquet Green’s function $\hat{G}(\omega, n)$. Here, $\hat{G}_{\alpha,\beta}(\omega, n)$ is nothing but a Fourier transform of the retarded Green’s function $G_{\alpha,\beta}^{R}(t, t')$. Starting from the usual definition of the retarded Green’s function,

$$G_{\alpha,\beta}^{R}(t, t') = -i\theta(t - t')\langle \hat{c}_{\alpha}(t)\hat{c}_{\beta}^\dagger(t') + \hat{c}_{\beta}^\dagger(t')\hat{c}_{\alpha}(t) \rangle$$

we take the Fourier transform to obtain

$$G_{\alpha,\beta}^{R}(t, \omega) = \int_{-\infty}^{\infty} dt' G_{\alpha,\beta}^{R}(t, t')e^{i(\omega + i\epsilon)(t-t')}.$$ \hspace{1cm} (10)

Because we are driving the system at the given frequency $\Omega$, this Green’s function, as a function of $t$, should contain only the discrete Fourier components. Therefore, we can expand as

$$G_{\alpha,\beta}^{R}(t, \omega) = \sum_{k=-\infty}^{\infty} G_{\alpha,\beta}(n, \omega)e^{-in\Omega t}$$ \hspace{1cm} (11)

The equation of motion followed by $\hat{G}(\omega, n)$ can be obtained by writing out the equation of motion for $G_{\alpha,\beta}^{R}(t, t')$ and taking its Fourier transform. Th resulting equation can be written in the most compact form in the matrix equation whose elements correspond to different (discrete) frequency components, $n\Omega$. Explicitly, the equation is given by

$$(\omega + \Omega - \mathbf{H} - i\Gamma/2)\mathbf{g} = \mathbf{I}$$ \hspace{1cm} (12)

where

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5.png}
\caption{a) Measurements of Faraday/Kerr rotations in three dimensional topological insulator. Circularly polarized light with a large frequency is used to open a gap at the Dirac point and linearly polarized light with small frequency within the gap is used to measure the Faraday/Kerr rotations. The polarization angle of the light is denoted by blue arrows in the figure. b) The induction of magnetic monopole inside a three dimensional topological insulator through the application of light. Electron charge is placed near the surface, and circularly polarized light is applied on the surface to break the time-reversal symmetry and open the effective gap. The magnetic monopole is induced as a mirror image of the electron charge.}
\end{figure}
in Section II.

This solution is derived by writing “Floquet Dyson’s equation,” and has the advantage of being numerically efficient. Again, by taking the off-resonant, weak intensity limit of this solution, we arrive the result reported in Section II. In Section III B, we derive the equivalence of non-external drivings where the system only possesses discrete external drivings where the system only possesses discrete photon absorptions/emissions. Also, this fact can be seen as a natural consequence of the breaking of continuous time-translation invariance through external drivings where the system only possesses discrete time-translation invariance under \( t \rightarrow t + T \). In the following, we assume that \(-\Omega/2 \leq E_a \leq \Omega/2\) without loss of generality. We take the normalization of Floquet states such that \( \sum_n \langle \varphi_a^n | \varphi_a^n \rangle = \delta_{ab} \). The Schrödinger equation for the Fourier components of the Floquet states is time-

\[
H = \begin{pmatrix} \vdots & \vdots & \ddots & \vdots \\ \hat{H}_0 & \hat{H}_1 & \cdots & \hat{H}_1 \\ \hat{H}_0 & \hat{H}_1 & \cdots & \hat{H}_1 \\ \hat{H}_0 & \hat{H}_1 & \cdots & \hat{H}_1 \\ \vdots & \vdots & \ddots & \cdots \\
\end{pmatrix}, \quad \Omega = \begin{pmatrix} \cdots & \cdots & \cdots & \cdots \\ 1\Omega & 0\Omega & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots \\
\end{pmatrix}
\]

\( H \) is the matrix of Hamiltonian, whose elements are the Fourier components of Hamiltonian given by \( \hat{H}_n = \frac{1}{T} \int_0^T \hat{H}(t) e^{i\Omega nt} \text{d}t \). \( \Omega \) is the diagonal matrix whose element is just the discrete frequency of the component. \( \Gamma \) is a diagonal matrix that represents coupling of the systems with leads. Its element \( \Gamma(\omega) \) has non-zero value only at site \( j_a \) that couples with leads, and with value \( \Gamma_{j_a,j_a}(\omega) = \Gamma_\alpha(\omega) = \Gamma_a^\rho_j(\omega) \). Finally, \( g \) is the matrix composed of the Floquet Green’s functions.

\[
\Gamma = \begin{pmatrix} \hat{\Gamma}(\omega + \Omega) \\ \hat{\Gamma}(\omega) \\ \hat{\Gamma}(\omega - \Omega) \end{pmatrix}, \quad g = \begin{pmatrix} \cdots & G(0,\omega) & G(1,\omega) & \cdots \\ \cdots & G(-1,\omega) & G(0,\omega) & G(1,\omega) & \cdots \\ \cdots & \cdots & \cdots & \cdots \end{pmatrix}
\]

\( B. \) Floquet states and Floquet Green’s functions

1. General relation

The “stationary states” of the Schrödinger equation for periodically driven systems are the states which return to themselves after one period of time, \( T = 2\pi/\Omega \), with possible phase accumulations. These so-called Floquet states are the eigenstates of the evolution operator over one period, and thus also eigenstates of effective Hamiltonian \( H_{\text{eff}} \) defined in Eq. (2). Green’s functions \( \tilde{G}(\omega, n) \) that describes the propagation of particles with possible absorptions/emissions of photons have natural expressions in terms of these Floquet states.

The time evolution of the Floquet states \( |\varphi_a(t)\rangle \) can be expanded in the discrete Fourier component of the driving frequency \( \Omega \), and can be expressed as

\[
|\varphi_a(t)\rangle = e^{-iE_a t} \sum_n e^{-i\Omega nt} |\varphi_a^n\rangle
\]

where \( E_a \) is the quasi-energy of the Floquet state \( |\varphi_a^n\rangle \) for \( H_{\text{eff}} \) and \( |\varphi_a^n\rangle \) is nth Fourier component of the Floquet state. The eigenstates of effective Hamiltonian \( H_{\text{eff}} \) are given as \( |\varphi_a\rangle = \sum_n |\varphi_a^n\rangle \). As one can see from the expression above, the quasi-energy \( E_a \) is only well-defined up to the driving frequency \( \Omega \), i.e. we can equally define \( E_a + m\Omega \) as the quasi-energy of \( |\varphi_a(t)\rangle \) by redefining \( |\varphi_a^n\rangle \rightarrow |\varphi_a^{n-m}\rangle \). Physically, this means the quasi-energy is only conserved up to the driving frequency \( \Omega \) because the system can absorb or emit photon energies. Also, this fact can be seen as a natural consequence of the breaking of continuous time-translation invariance through external drivings where the system only possesses discrete time-translation invariance under \( t \rightarrow t + T \). In the following, we assume that \(-\Omega/2 \leq E_a \leq \Omega/2\) without loss of generality. We take the normalization of Floquet states such that \( \sum_n \langle \varphi_a^n | \varphi_a^n \rangle = \delta_{ab} \). The Schrödinger equation for the Fourier components of the Floquet states is time-
independent,

\[(E_a + n\Omega)|\varphi_a^n\rangle = \sum_{m} H_{n-m}|\varphi_a^m\rangle \quad (15)\]

where \(H_n\) is the discrete Fourier component of Hamiltonian, i.e. \(H_n = \frac{1}{T} \int_{0}^{T} H(t)e^{-i\Omega n t} dt\). This equation encapsulates the evolution of states that allows the absorptions/emissions of photons; application of Hamiltonian \(H_m\) leads to the absorption of \(m\) photons and the state \(|\varphi^n\rangle\) is the component of the state with \(n\) photons. Here we considered the evolution of the systems in the absence of coupling with leads, but in the presence of the coupling with leads, zero frequency component of the Hamiltonian \(H_0\) contains the imaginary "leaking" term \(i\Gamma/2\).

This Schrödinger equation takes, in the matrix form,

\[E_a|\varphi_a\rangle = (-\Omega + H)|\varphi_a\rangle \quad (16)\]

where

\[|\varphi_a\rangle = \begin{pmatrix} |\varphi_a^0\rangle \\ |\varphi_a^1\rangle \\ \vdots \end{pmatrix} \quad (17)\]

The Hamiltonian matrix \(H\) and driving frequency matrix \(\Omega\) are given in Eq. (13).

Thus, Floquet state \(|\varphi_a\rangle\) is nothing but the eigenstates of the composite Hamiltonian \((-\Omega + H)\). Notice that "shifted" state

\[|\varphi_a^\text{shift}(n)\rangle = \begin{pmatrix} |\varphi_a^{n+1}\rangle \\ |\varphi_a^n\rangle \\ |\varphi_a^{n-1}\rangle \\ \vdots \end{pmatrix} \quad (18)\]

is also an eigenstate with eigenvalue \(E_a + n\Omega\).

Now we can relate the Floquet eigenstates given by Eq. (16) and Floquet Green’s function given by Eq. (12). The formal solution of Eq. (12) is obtained in terms of the eigenstates \(|\varphi_a\rangle\) of the matrix \((-\Omega + H - i\Gamma/2)\) as

\[G = \sum_a \frac{|\varphi_a\rangle\langle\varphi_a|}{\omega - \varepsilon_a} \quad (19)\]

Here, \(\langle\varphi_a|\varphi_b\rangle\) is the state that is determined from \(\langle\varphi_a|\varphi_b\rangle = \delta_{ab}\). (Note that in the presence of \(i\Gamma/2\), \(\langle\varphi_a|\varphi_b\rangle\) is not just a complex conjugate of \(|\varphi_a\rangle|\langle\varphi_b|\).

As is clear from Eq. (16), the eigenstates \(|\varphi_a\rangle\) of the matrix \((-\Omega + H - i\Gamma/2)\) is nothing but the Floquet states in the presence of the coupling with leads, represented by \(-i\Gamma/2\). Notice that the eigenstates \(|\varphi_a\rangle\) in Eq. (19) include all the shifted states \(|\varphi_a^\text{shift}(n)\rangle\) in Eq. (18) for all integers \(n\). With this understanding, we obtain the expression of the Floquet Green’s function \(G(n,\omega)\) as

\[G(n,\omega) = \sum_{a,m} \frac{|\varphi_a^{n-m}\rangle\langle\varphi_a^{-m}|}{\omega - E_a - m\Omega} \quad (20)\]

We can see that Floquet Green’s function is an intuitive extension of the Green’s function for free electrons that allows absorptions and emissions of photons. As is expected, this Green’s function transfers the state in \(-m\) photon sector \(|\varphi_a^{-m}\rangle\) to \(n - m\) photon sector \(|\varphi_a^{n-m}\rangle\) by absorbing \(n\) photons.

In the presence of on-resonant light, Floquet states generally contain non-zero amplitudes in \(|\varphi_a^n\rangle\) for more than one value of \(n\), and therefore, the contributions to the response current in Eq. (5) from a few photon absorptions/emissions are non-zero. Thus effective static Hamiltonian or band structures, which are only the description of average of \(n\) photon states \(\sum_n |\varphi_a^n\rangle\), does not appropriately capture transport properties under the on-resonant light. In this case, it is necessary to compute the full Floquet Green’s function given by Eq. (20) and calculate the response current in Eq. (7).

On the other hand, in the case of off-resonant, weak intensity of light, transport properties of non-equilibrium systems can be described by an effective photon-dressed Hamiltonian. In the next section, we provide the proof in the case of semi-metals such as graphene and topological insulators.

2. Effective Hamiltonian description

As summarized in Section II, a rich physics appears when circularly polarized light is applied to graphene and topological insulators. The description of the non-equilibrium transport takes a particularly simple form for the off-resonant light in the limit of small light intensity \(A \ll 1\). Here we apply the general formalism developed in the previous section to these systems and study the transport property by obtaining the Floquet Green’s function in Eq. (20).

From the explicit form of the Hamiltonian in Eq. (1), it is clear that \(H_n \sim O(A^n)\). This simply means the absorptions of photons are suppressed by the factor \(O(A^n)\). Thus, the \(n\) photon sectors of the Floquet states \(|\varphi_a^n\rangle\) are expected to scale as \(|\varphi_a^n\rangle \sim O(A^n)\) with zeroth order solution being the static part of the Hamiltonian \(H_0 + i\Gamma/2\). Here the term \(i\Gamma/2\) represents the coupling with leads and we assumed the same strength of the coupling \(\Gamma = \Gamma_n\) at each lead \(\alpha\) and further assumed that it is independent of frequency. This latter assumption is not important in the off-resonant case because current is essentially conducted only at chemical potential of leads, as we will confirm later. Starting from the equation Eq. (15), we apply a degenerate perturbation theory
in the lowest non-trivial order in $\mathcal{A}$ to obtain

$$
\left(H_0 + i\Gamma/2 + \frac{[H_{-1},H_1]}{\Omega}\right)|\varphi^0_n\rangle = E_n|\varphi^0_n\rangle \quad (21)
$$

$$
|\varphi^0_n\rangle = \frac{1}{n\Omega} H_n|\varphi^0_n\rangle \quad \text{for } n \neq 0
\quad (22)
$$

In the derivation, we assumed $E_n \ll \Omega$, so the expression above is only valid near the Dirac points. Note that since the Hamiltonian $H_0$ is degenerate at the Dirac points, the mixings of the states due to the perturbations of $\mathcal{A}$ are not small. This result indeed shows that $|\varphi^0_n\rangle \sim O(\mathcal{A}^{|n|})$, and therefore, the Floquet states $|\varphi^0_n\rangle$ can be approximated by the zeroth level of the Floquet states $|\varphi^0_n\rangle$, which is given by the eigenstates of the effective Hamiltonian $H_{\text{eff}} = H_0 + \frac{[H_{-1},H_1]}{\Omega}$ plus the coupling with leads $i\Gamma/2$.

Using the solution of Floquet states above, we can obtain the response current in the lowest order in $\mathcal{A}$. The scaling $|\varphi^0_n\rangle \sim O(\mathcal{A}^{|n|})$ in Eq. (22) directly implies that $|\tilde{G}(n,\omega)|^2 \sim O(\mathcal{A}^{2n})$. Moreover, Green’s function with no photon absorptions or emissions can be approximated as

$$
\tilde{G}(0,\omega) = \sum_a \frac{|\varphi^0_a\rangle \langle \varphi^0_a|}{\omega - E_a} + O(\mathcal{A}^2)
$$

$$
\equiv \tilde{G}^{\text{eff}}(\omega) + O(\mathcal{A}^2)
$$

where $|\varphi^0_a\rangle$ is the eigenstates of $H_{\text{eff}} + i\tilde{\Gamma}/2$, and therefore $\tilde{G}^{\text{eff}}(\omega)$ is the free electron Green’s function for the static system with Hamiltonian $H_{\text{eff}}$ coupled with leads. Thus, these arguments combined with the expressions of currents in Eq. (7) and Eq. (8) prove that the many-terminal measurements of non-equilibrium systems under the off-resonant light give the same result as if the system is given by the static effective Hamiltonian $H_{\text{eff}}$. We emphasize that this result immediately implies the following two facts: 1. the non-equilibrium system displays insulating behaviors in the longitudinal conductance 2. Hall conductance is nearly quantized with possible correction of $O(\mathcal{A}^2)$, as presented in Section II.

3. Insulating behavior for gapped effective Hamiltonian $H_{\text{eff}}$

In the analysis of the previous section, we established the insulating behaviors of graphene under the application of off-resonant light through the perturbation theory in $\mathcal{A}$. Such analysis only shows that the longitudinal conductivity is small and of the order of $\mathcal{A}^2$, but does not show, in a strict sense, that the conductivity goes to zero at zero temperature. Using the formalism developed in previous sections, it is possible to show that the non-equilibrium system is an insulator for all orders in $\mathcal{A}$ as long as the chemical potential of leads lies below the effective gap of $H_{\text{eff}}$. The argument does not rely on the off-resonant condition and in principle applicable whenever $H_{\text{eff}}$ has a gap.

Here we consider an infinite plane of graphene, and we attach $N_L$ number of leads as "left" leads and $N_R$ number of leads as "right" leads, where these leads are separated by a large distance, see Fig. 6. Here we assume that the leads are coupled with the system with equal strength, given by $\Gamma(\omega)$. For clarity, we consider the situation in which the chemical potentials of the reservoirs connected to left leads are at $V/2$ and those of the reservoirs connected to the right leads are at $-V/2$ with $|V| \ll J$.

In the limit of small coupling strength, the Green’s function in Eq. (20) can be obtained through the perturbation theory on $\Gamma$, and are given by

$$
\tilde{G}(n,\omega) \approx \sum_a \sum_m \frac{|\varphi^0_a\rangle \langle \varphi^0_m|}{\omega - E_a - m\Omega - i\gamma_a(\omega)}
$$

where $\gamma_a(\omega) = \sum_n \langle \varphi^0_a|\tilde{\Gamma}(\omega+n\Omega)/2|\varphi^0_n\rangle$, and $|\varphi^0_n\rangle$ and $E_n$ are the Floquet states and (quasi-)energies of the system in the absence of the coupling with leads. In the limit of small $\gamma_a(\omega)$, the square of the Green’s function $\tilde{G}(n,\omega)$ can be approximated by a delta function, so that the transmission probability also becomes a delta function in frequency:

$$
T_{L,R}(n,\omega) = \sum_{L_i,R_i} \sum_{a,m} \Gamma(\omega)\Gamma(\omega+n\Omega)
$$

$$
\times \frac{|\langle j_{L_i}|\varphi^0_{n-m}\rangle|^2}{2\gamma_a(\omega)} \langle \varphi^0_{n-m}|j_{R_i}\rangle^2 \pi\delta(\omega - E_a - m\Omega)
$$

where $j_{L_i}(R_i)$ are the sites of left (right) leads. Now note that the (quasi-)energies $E_n$ are the eigenvalues of $H_{\text{eff}}$ in Eq. (2) in the main text. Therefore, if all
the chemical potentials lies within the gap of \( H_{\text{eff}} \), i.e. \(|V| \leq \Delta\), the delta function gives zero everywhere for \(-V/2 \leq \omega \leq V/2\). Note that we have taken the quasienergies \( E_{\omega} \) to lie between \(-\Omega/2 \leq E_{\omega}\Omega/2\) and thus, by assumption, \( \Delta \leq \Omega \). \( m\Omega \) term plays no role in the conduction. Thus, from the expression of the DC current in Eq. (24), it is clear that the current has to be zero when \(|V| \leq \Delta\).

The argument above is general and did not require the condition of off-resonance. In the case of on-resonant light, the effective band structures are given by mixing the static eigenstates whose energies differ by \( \Omega \). This "folding" of the band structures generically leads to a large number of states appearing in the effective Hamiltonian near the chemical potential, and subsequently the effective gap in \( H_{\text{eff}} \) becomes proportional to \( O(\Delta^n) \) with \( n \) approximately determined by the ratio of the static band width and the driving frequency \( \Omega \). While the insulating behavior should be observable in the small window of the gap, the gap could be small in this case.

C. Floquet Dyson’s equation

In this section, we present yet another way to obtain the Floquet Green’s function \( \hat{G}(n, \omega) \) which gives an efficient way to numerically evaluate the Floquet Green’s function for a certain class of periodical drives.

In this section, we consider the Hamiltonian that depends only on the first harmonics of the driving frequency \( \Omega \), namely, the Hamiltonian takes the form

\[
H(t) = H_0 + V_1 e^{-i\Omega t} + V_{-1} e^{i\Omega t}. \tag{24}
\]

For example, for the application of the circularly polarized light to two dimensional lattice systems, \( V_1 = \sum_j (x_j + i y_j) c_j^\dagger c_j \) and \( V_{-1} = V_1^\dagger \) in the gauge in which the light is represented as a circulating potential. However, in this gauge, \( V_{\pm 1} \) diverges as \( x_j, y_j \rightarrow \infty \), care must be taken to study with this gauge. Conceptually useful gauge is the gauge in which the effect of light is represented as a phase accumulation as in Section II. For weak amplitude of light, we can approximate the Hamiltonian in this gauge in the form of Eq. (24) with \( V_1 = H_1 \) and \( V_{-1} = H_{-1} \). As before, we are interested in the terminal measurements of conductance, and thus assume that the static part of the Hamiltonian \( H_0 \) contains the "leaking" of particles into leads given by \( i\Omega(\omega)/2 \).

In order evaluate Floquet Green’s functions, we first rewrite the equation Eq. (12) in the suggestive form of

\[
\hat{G}(n, \omega) \rightarrow \delta_{n_0} + V_1 \hat{G}^0(n, \omega) \rightarrow \hat{G}^0(n, \omega) \cdot \hat{G}(n+1, \omega) + V_1 \hat{G}(n-1, \omega)
\]

FIG. 7: The Floquet Dyson equation. The propagator goes from right to left. Double line represents the full propagator \( \hat{G}(n, \omega) \) and single line is a bare propagator \( \hat{G}^0(n, \omega) \) which does not include the effect of photon absorptions.

"Floquet Dyson’s equation" (see Fig. 7);

\[
\hat{G}(n, \omega) = \delta_{n_0} \hat{G}^0(n, \Omega) + \hat{G}^0(n, \Omega) \left( V_{-1} \hat{G}(n+1, \omega) + V_1 \hat{G}(n-1, \omega) \right)
\]

(25)

Here \( \hat{G}^0(n, \Omega) = \frac{1}{\omega + n\Omega - H_0} \) represents the bare propagator of a particle with \( n \) photons. This equation has the intuitive understanding of the full propagator \( \hat{G}(n, \omega) \) that represents the \( n \) photon absorption process as being composed of the full propagation of \( \hat{G}(n \pm 1, \omega) \) followed by the absorption or emission of a photon, followed by the propagation of the bare particle.

A particularly elegant solution for \( \hat{G}(n, \omega) \) is provided by continued fraction method\textsuperscript{17}. The building block of the solution is the dressed propagator

\[
\hat{F}_+(n, \omega) = \frac{1}{(G^0)^{-1}(n, \omega) - V_{-1}^{-1} F_+(n+1, \omega) - V_1^{-1}}
\]

for \( n > 0 \)

\[
\hat{F}_-(n, \omega) = \frac{1}{(G^0)^{-1}(n, \omega) - V_1^{-1} F_-(n-1, \omega) - V_{-1}^{-1}}
\]

for \( n < 0 \)

The propagator \( \hat{F}_+(n, \omega) \) is dressed only from the higher photon number states, and the propagator \( \hat{F}_-(n, \omega) \) is dressed by the lower photon number states. The full propagator is then given as

\[
\hat{G}(0, \omega) = (\omega - H_0 - V_{\text{eff}})^{-1}
\]

(26)

\[
V_{\text{eff}} = V_1 \hat{F}_-(1, \omega) V_{-1} + V_{-1} \hat{F}_+(1, \omega) V_1
\]

\[
\hat{G}(n, \omega) = \hat{F}_+(n, \omega) V_1 \cdots \hat{F}_+(1, \omega) V_1 \hat{G}(0, \omega)
\]

for \( n > 0 \)

\[
\hat{F}_-(n, \omega) V_{-1} \cdots \hat{F}_-(1, \omega) V_{-1} \hat{G}(0, \omega)
\]

for \( n < 0 \)

(27)

This solution is valid for any driving frequency. Remarkably, we see that the zero-photon absorption propagator \( \hat{G}(0, \omega) \) is simply given by the propagator in an effective Hamiltonian \( H_{\text{eff}} = H_0 + V_{\text{eff}} \).
For the gauge in which light is represented as time-dependent vector potential, and weak intensity of light $A \ll 1$, we can approximate $\hat{F}_{\pm}(1, \omega) = \hat{F}_{\pm}(-1, \omega) = \frac{1}{\Omega}$ in the limit of high frequency. Thus, we reproduce the result we obtained in Section III B 2 of the effective Hamiltonian $H_{\text{eff}} = H_0 + \frac{[H^{\text{ph}}, H_0]}{\Omega}$ in this limit.

IV. EFFECT OF ELECTRON-ELECTRON AND ELECTRON-PHONON INTERACTIONS

The non-equilibrium transport properties described in Section II are robust against interactions such as electron-electron interactions, interactions between electrons and disorder, and electron-phonon interactions. The electron-electron interactions only renormalize the velocity of Dirac electrons, $v_G$ and $v_{\text{IT}}$, and do not change the Dirac nature of the electrons near the Fermi surface. The quantum Hall insulators are insensitive to disorders due to the topological origin of the phase, as long as the disorder strength is small compared to the gap size, $\Delta$. The robustness of the phenomena against phonon scatterings originates from the conservation of energy in $H_{\text{eff}}$ up to the light frequency $\Omega$. When the chemical potentials of leads lie in the gap of $H_{\text{eff}}$, the non-equilibrium current in many-terminal measurements is conducted through electrons in the lower band of $H_{\text{eff}}$. Such current can degrade due to electron-phonon interactions if electrons in the lower band can be excited to the higher band. However, such excitations in the bands of effective Hamiltonians require a physical energy greater than the gap $\Delta$ as is rigorously established in "Floquet Fermi golden rule" in Appendix A. It is in principle possible to absorb energies from photons, but because the frequency of photons $\Omega$ is assumed to be much larger than band width, the absorption of such large energy requires the excitations of electrons together with many phonons, and therefore such a process is suppressed. Thus, the transition of an electron from the lower band of the effective Hamiltonian to the higher band is possible only through the absorption of phonon energies. Therefore, at low temperatures, the property of an "insulating" state of the effective Hamiltonian is protected against electron-phonon interactions by the gap.

V. PROBE OF THE INDUCED EFFECTIVE GAP IN AN ISOLATED SYSTEM

In this section, we propose a different way to probe the effective gap induced by off-resonant light through the pump and probe measurements in an isolated system. The essential idea is simple. Given a system under the application of light (called pump laser), suppose that the effective Hamiltonian $H_{\text{eff}}$ defined by Eq. (2) has a gap $\Delta$. We prepare the state, in isolation from thermal reservoirs, such that only the lower band of $H_{\text{eff}}$ is occupied through a sort of "adiabatic preparation." Here we start from zero-temperature static system, and increase the intensity of light gradually to increase the size of the gap, $\Delta$. As we argue below and Appendix A, adiabatic theorem in Floquet picture guarantees that the final state has the electron occupations such that the lower band of photon-dressed Hamiltonian $H_{\text{eff}}$ is occupied. Now for this occupation of electrons with a gap to a higher band, it is intuitively clear that the system becomes transparent to the probe light with frequency smaller than $\Delta$. In the case of graphene and topological insulators under the application of light, we expect that the transmitted probe light results in the Faraday rotations.

The pump and probe measurements described above are well-understood if the modification of the system from the original Hamiltonian to final Hamiltonian $H_{\text{eff}}$ is done through a static fields. In this case, the adiabatic preparation is guaranteed by adiabatic theorem, and the transmission of probe light can be confirmed by looking at the Fermi golden rule which shows that the photons cannot be absorbed by electrons due to the conservation of energy.

In the case of periodically varying fields, analogous statements hold. "Floquet adiabatic theorem" shows that, under an adiabatic evolution of the periodically varying fields, each Floquet state follows the instantaneous Floquet state given by the instantaneous Hamiltonian. Similarly, "Floquet Fermi golden rule" gives the rate in which the transition from one Floquet state to another happens under small perturbations. This result shows that the quasi-energies of Floquet states are conserved up to integer multiples of driving frequency $\Omega$. Thus as we have claimed above, the electrons in the lower band of $H_{\text{eff}}$ cannot be excited to higher bands unless the photon energy is larger than the band gap $\Delta$. We give the detailed proof of these theorems in the Appendix A.

VI. CONCLUSION

In this paper, we studied the transport properties of non-equilibrium systems under the application of light in many-terminal measurements. Starting from Floquet-Landauer formula, we gave two different solutions of Floquet Green's functions that illustrate the physical origin of transport in this situation. We found that for generic driving frequencies, the transport involves photon-assisted conductance and cannot be described by any static, effective Hamiltonians.

In the case of graphene and topological insulators under the off-resonant light, the non-equilibrium transport does not involve photon absorptions/emissions. Rather, the electron band structures are modified through the virtual photon absorption/emission processes. We established, through the solution of Floquet Green's function, that such modifications are captured by the static photon-dressed Hamiltonian, and that the transport in this system becomes equivalent to that described by the photon-dressed Hamiltonian. Remarkably, the effective
Hamiltonian obtained in this way takes the form of Hal- 
dane model with second neighbor hopping with phase accu- 
cumulations for graphene under the application of cir- 
cularly polarized light.

One important aspect of our proposal is the opening 
of the gap in the photon-dressed Hamiltonian when the 
original static Hamiltonian is semi-metal and gapless. We 
gave two physical manifestations of such a gap. One is 
the insulating behavior of the driven system attached to 
the leads (Section III B 3). The attachment of leads is cru- 
cial to determine the electron occupation numbers. An- 
other is the transmission of low frequency light in an iso- 
lated system(Section V) after the adiabatic preparations 
of states. We argued the possibility of such pump-probe 
measurements by establishing two important extensions 
of well-known theorems, "Floquet adiabatic theorem" an 
"Floquet Fermi golden rule" (Appendix A).

The formalism and intuitive understanding developed 
in this paper can be used to study the transport prop- 
erties of a variety of systems under the application of light. 
It is of interests to analyze, for example, the transport 
properties of light-induced topological systems proposed 
in Ref. [10]. In addition, our analysis shows that transport 
under the application of light contains richer physics than 
static transport. In particular, photon-assisted con- 
ductance in which electrons absorbs/emits photons dur- 
ing the propagations is the unique feature of driven sys- 
tems, and it is interesting to analyze how such physical 
process results in energy conduction. While we focused 
on the response current \( J_{\text{res}} \) in this paper, yet another 
aspect of driven systems is the presence of pump current 
\( J_{\text{pump}} \) appearing in Eq. (4). It is of interests to find ma- 
terials that can pump currents by simply shining light on 
their surface.

lows.

Appendix A: Floquet Fermi golden rule and Floquet 
adiabatic theorem

In this section, we establish the following two state- 
ments about \( H_{\text{eff}} \) studied in the main text; 1) The result 
of many-terminal measurements of the systems under 
the application of light obtained in the main text is robust 
against electron-phonon interactions, as long as the en- 
ergy of phonons dictated by the temperature of the sys- 
tems is smaller than the induced gap \( \Delta \); 2) The photo- 
induced gap \( \Delta \) can be probed, in a closed system, by the 
transmission of a laser with frequency \( \omega < \Delta \).

We give arguments for the first statement by deriving 
an analogous theorem as Fermi golden rule in the period- 
ically driven systems. When the chemical potentials of 
leads lie in the gap of \( H_{\text{eff}} \), the non-equilibrium current in 
many-terminal measurements is conducted through elec- 
trons in the lower band of \( H_{\text{eff}} \). Such current can de- 
grade due to electron-phonon interactions if electrons in 
the lower band can be excited to the higher band. By 
deriving "Floquet Fermi golden rule," we demonstrate 
that such excitations in the bands of effective Hamilto- 
nians still require a physical energy greater than the gap 
\( \Delta \). It is in principle possible to absorb energies from 
photons, but because the frequency of photons \( \Omega \) is as- 
sumed to be much larger than band width, the absorp- 
tion of such large energy requires the excitations of elec- 
trons and many phonons, and therefore such a process 
is suppressed. Thus, the transition of an electron from 
the lower band of the effective Hamiltonian to the higher 
band is possible only through the absorption of phonon 
energies. Therefore, at low temperatures, the property of 
an "insulating" state of the effective Hamiltonian is pro- 	ected against electron-phonon interactions by the gap.

The proof of the second statement requires two steps. 
If we assume that the closed system with \( H_{\text{eff}} \) can be 
presented in a state such that only the lower band of \( H_{\text{eff}} \) 
is occupied, then we can argue from the "Floquet Fermi 
golden rule" that the low frequency laser with \( \omega < \Delta \) 
cannot be absorbed by the electrons. Therefore, such a 
system is transparent to the light. In order to prepare 
such a "filled" state of the effective Hamiltonian \( H_{\text{eff}} \), 
we consider an adiabatic preparation. Starting from 
the half-filled state of original systems whose chemical po- 
tential lies at the Dirac points, we adiabatically increase 
the strength of light. We argue, by deriving "Floquet 
adiabatic theorem," that such procedure prepares the 
filled state of \( H_{\text{eff}} \) except possibly exactly at the Dirac 
points.

These two statements rely on two general theorems 
about periodically driven systems, dubbed as "Floquet 
Fermi golden rule" and "Floquet adiabatic theorem." In 
the following, we derive these results, using the elegant 
approach from "two-time" formalism. We emphasize 
that these results are general and have wide applications 
outside of what we discussed in this paper.

1. Two-time Schrödinger equation

In order to study the dynamics of periodically driven 
systems, it is convenient to separate two time scales, a 
fast time scale associated with the driving frequency \( \Omega \) 
and a slow time scale associated with other dynamics 
such as those of phonons. We let \( t \) denote the former 
time scale and \( \tau \) the latter, and obtain the Schrödinger 
equation of the slower dynamics in terms of \( \tau \) through 
the replacement \( i\partial/\partial t \rightarrow i\partial/\partial \tau + i\partial/\partial \tau \). Then the time
The evolution of states for slow time scale can be written as
\[ i \frac{\partial}{\partial t} |\psi(\tau)\rangle = \left( \mathcal{H} + \hat{V}(\tau) \right) |\psi(\tau)\rangle \] (A1)
\[ \mathcal{H} = H(t) - i \frac{\partial}{\partial t} \] (A2)
where \( H(t) \) corresponds to the Hamiltonian with periodic drives with frequency \( \Omega \) and \( \hat{V}(\tau) \) represents the perturbation of the system with slow frequencies compared to \( \Omega \). In the absence of the perturbation \( \hat{V}(\tau) \), the eigenstates of the Schrödinger equation above is given by Floquet states such that
\[ E_\alpha |\Phi_\alpha\rangle = \mathcal{H}|\Phi_\alpha\rangle \] (A3)
where \( |\Phi_\alpha(t)\rangle = e^{iE_\alpha t} |\varphi_\alpha(t)\rangle = \sum_n e^{-i\Omega nt} |\varphi_\alpha^n\rangle \) is a state with a periodic structure \( |\Phi_\alpha(t)\rangle = |\Phi_\alpha(t+T)\rangle \), and \( E_\alpha \) is the quasi-energy of the Floquet state, i.e. the eigenenergy of \( H_{\text{eff}} \). Here \( |\varphi_\alpha(t)\rangle \) represents a Floquet state which satisfies the equation \( \mathcal{H}|\varphi_\alpha(t)\rangle = 0 \). Note that \( E_\alpha \) is only defined up to \( \Omega \), so that physically the same Floquet state \( |\varphi_\alpha(t)\rangle \) in Eq. (14) can be associated with the eigenvalue \( E_\alpha + m\Omega \) and the state \( |\Phi_\alpha^m(t)\rangle = \sum_n e^{-i\Omega nt} |\varphi_\alpha^{n+m}\rangle \). Here we take the convention that \( |\Phi_\alpha^m(t)\rangle \) with \( m = 0 \) is associated with the quasi-energy \( E_\alpha \) such that \( -\Omega/2 \leq E_\alpha \leq \Omega/2 \). The orthogonality of the eigenstates \( |\Phi_\alpha\rangle \) can be recovered by defining the inner product of Floquet states as the average of the usual inner product over one period of time,
\[ \langle \langle \chi_\alpha | \chi_\beta \rangle \rangle = \frac{1}{T} \int_0^T \langle \chi_\alpha(t) | \chi_\beta(t) \rangle dt. \] (A4)

Then we have \( \langle \langle \Phi_\alpha(t) | \Phi_\beta(t) \rangle \rangle = \delta_{\alpha,\beta} \).

These extensions of the inner products and eigenvalue problem in periodically driven systems can be considered as the extension of Hilbert space to include the fast time variable \( t \) as another "spatial" variable. The inner product Eq. (A4) in this Hilbert space integrates over \( t \), and the time variable is now represented by the slow time variable \( \tau \). We point out that the inner product Eq. (A4) makes sense only when any dynamics associated with \( \tau \) occurs in a slow time scale than the period of driving \( T \). In principle, operators and states which depend on \( \tau \) change during the integration time \( T \) of fast time variable \( t \) due to the dependence on \( \tau \). Since we are treating \( t \) and \( \tau \) as independent variables, the inner product Eq. (A4) ignores such \( \tau \) dependence. As long as such changes are small, the inner product Eq. (A4) gives a good approximation.

The crucial observation is that the slow time Schrödinger equation in Eq. (A1) has the identical form as the usual Schrödinger equation, and therefore, many results for static systems can be directly extended to periodically driven systems through the extension of the the inner product to Eq. (A4).

### 2. Floquet Fermi golden rule

"Floquet Fermi golden rule" gives the intuition behind the response of periodically driven systems under the influence of perturbations. In particular, the result shows that quasi-energy of the effective Hamiltonian \( H_{\text{eff}} \) is a conserved quantity up to the driving frequency \( \Omega \). In the context of our paper, this result implies electrons in the lower band of \( H_{\text{eff}} \) cannot be excited to the upper band if the frequencies of the perturbations, such as phonons or probe light, are smaller than the gap \( \Delta \). Thus the transport property of a non-equilibrium system described by \( H_{\text{eff}} \) is robust against phonon interactions as long as the chemical potentials of leads lie in the gap and phonon energies are smaller than the gap \( \Delta \). Moreover, if one can prepare the system in the state with filled lower band of \( H_{\text{eff}} \), then the gap of \( H_{\text{eff}} \) can be probed by observing the transmissions of low frequency lasers.

This "Floquet Fermi golden rule" can be easily obtained through the "two-time" formalism described in the previous section. In the following, we consider the perturbations of the system such as phonons with frequency \( \omega \) much smaller than \( \Omega \) such that \( \omega \ll \Omega \). We take the perturbation in the form \( \hat{V}(\tau) = \hat{V} e^{-i\omega \tau} \). The usual derivation of Fermi golden rule can be applied in a straightforward fashion, and we obtain "Floquet Fermi golden rule", which gives the rate \( \gamma_{\text{init}} \) of exciting the initial Floquet state \( |\varphi_i\rangle \) to the final Floquet state \( |\varphi_f\rangle \) in the presence of the perturbation \( \hat{V}(\tau) \);

\[ \gamma_{\text{init}} = \sum_m |\langle \langle \Phi_\alpha^m | \hat{V} | \Phi_\alpha^0 \rangle \rangle|^2 \delta(E_i + \omega - E_f - m\Omega). \] (A5)

Here \( E_i \) and \( E_f \) are the quasi-energies of the initial and final Floquet states, respectively. In order to derive the result above, we represented the Floquet state \( |\varphi_i\rangle \) by the specific periodic state \( |\Phi_\alpha^0\rangle \). This choice is arbitrary and any other choice gives the same result. Since the physical Floquet state \( |\varphi_i\rangle \) can be represented as the states \( |\Phi_\alpha^m\rangle \) for any integers \( m \), the total transition rate is given by the sum of the rate from the state \( |\Phi_\alpha^0\rangle \) to states \( |\Phi_\alpha^m\rangle \).

This rate has the same form as the conventional Fermi golden rule, except for the summation over the Floquet energy index \( m \). The delta function in the equation above imposes the conservation of quasi-energy which is the eigenenergy of effective Hamiltonian \( H_{\text{eff}} \), which means the energy is conserved up to the driving frequency \( \Omega \). This is a natural consequence of the fact that the system can absorb or emit the energy \( \Omega \) from the periodic drives.

From this result, it is clear that such conservation of quasi-energy prevents the excitations of electrons from lower band to upper band when phonon energy \( \omega \) is smaller than the gap of the system, and \( \Omega \) is much larger than the total band-width of electrons.
3. Floquet adiabatic theorem

In this subsection, we show, in analogy with the adiabatic theorem of static systems, that a Floquet state follows an adiabatic change of Hamiltonian and stays in the Floquet state of the instantaneous Hamiltonian. This result indicates that the adiabatic increase of the intensity of light can be used to prepare the state with filled lower band of $H_{\text{eff}}$, whose properties can then be probed through low frequency lasers as argued above.

Starting from the slow time Schrödinger equation in Eq. (A1), we can follow the derivation of adiabatic theorem and prove the analogous theorem for periodically driven systems. Here we briefly outline the derivation.

Suppose that the total Hamiltonian $H(\tau)$ is slowly varying as a function of $\tau$. We are interested in how a Floquet state of $H(0)$ at time $\tau = 0$ evolves under this time evolution. Let $|g\rangle$ be the initial Floquet state and $\langle g|G(\tau)\rangle$ be the result of evolving $|g\rangle$ under $H(\tau)$ for time $\tau_0$.

We denote the instantaneous eigenstates of $H(\tau)$ as $|\alpha(\tau)\rangle$ such that $H(\tau)|\alpha(\tau)\rangle = E_{\alpha}(\tau)|\alpha(\tau)\rangle$. Then we express the state $|G(\tau)\rangle$ in terms of $|\alpha(\tau)\rangle$ as

\[ |G(\tau)\rangle = \exp\left(-i \int_{0}^{\tau} E_g(\tau')d\tau'\right) \times \left(c_g(\tau)|g(\tau)\rangle + \sum_{\alpha \neq g} c_\alpha(\tau)|\alpha(\tau)\rangle\right) \] (A6)

In the absence of degenerate states, we can solve for the coefficients $c_\alpha(\tau)$ in the lowest order for the slow change of Hamiltonian $H(\tau)$ in the Schrödinger equation of Eq. (A1). The result is given by

\[
|G(\tau)\rangle = e^{-i \int_{0}^{\tau} E_g(\tau') d\tau'} \exp \left(-i \int_{0}^{\tau} i \langle g(\tau') | \frac{\partial}{\partial \tau} | g(\tau') \rangle d\tau' \right) \left(|g(\tau)\rangle - i \sum_{\alpha \neq g} |\alpha(\tau)\rangle \frac{\partial \langle \alpha(\tau) | g(\tau) \rangle}{\partial E - E_g(\tau)} \right)
\] (A7)

Thus to the zeroth order for the slow change of Hamiltonian $H(\tau)$, $|G(\tau)\rangle$ is the Floquet state of the instantaneous Hamiltonian $H(\tau)$ with possible accumulations of dynamical and Berry phases. The first order correction is given by the second term of Eq. (A7).

For static systems of Dirac Fermions studied in this paper, we have shown that a gap proportional to $A^2$ opens at the Dirac point upon the application of light. If the chemical potential lies at the Dirac point before the application of light, the result above implies that the adiabatic increase of the intensity of light $A(\tau)$ can be used to prepare the system close to the filled lower band state of $H_{\text{eff}}$. At exactly the Dirac points where the spectrum becomes degenerate, the adiabatic theorem above does not apply, but these points represent only a tiny portion of the total states, and thus can be ignored for the calculations of physical quantities. When the initial system is at finite temperature, such adiabatic increase of $A(\tau)$ leads to non-thermal distributions of electrons in the spectrum of $H_{\text{eff}}$, but nonetheless the resulting density matrix can be calculated through the result Eq. (A7) in the adiabatic limit.

This Floquet adiabatic theorem can be used to obtain the Kubo's formula\textsuperscript{25} in the non-interacting, periodically driven systems. In Ref.[9], such result is applied to derive the extension of TKNN formula\textsuperscript{26} to periodically driven systems in infinite systems.
