(Dated: November 29, 2011)

Recent spin-Seebeck experiments on thin ferromagnetic films apply a temperature difference $\Delta T_x$ along the length $x$ and measure a (transverse) voltage difference $\Delta V_y$ along the width $y$. The connection between these involves: (1) thermal equilibration between sample and substrate; (2) spin currents along the height (or thickness) $z$; and (3) the measured voltage difference $\Delta V_y$. The present work models in detail the first of these steps, and outlines how to obtain the other two. In 1D, thermal equilibration between the magnons and phonons in the sample, as well as additional equilibration between the sample and the substrate, leads to two surface modes, with lengths $\lambda$, to provide thermal equilibration. Increasing the coupling between the two modes increases the longer mode length and decreases the shorter mode length. In 2D, the applied thermal gradient along $x$ leads to a thermal gradient along $z$ that varies as $\sinh(x/\lambda)$, which produce fluxes along $z$ of the up- and down-spin carriers, and gradients of their associated magnetoelectrochemical potentials $\mu_{\uparrow,\downarrow}$, which vary as $\sinh(x/\lambda)$. There is also an infinite spectrum of shorter lengths $\lambda$ that are geometrically determined. By the inverse spin Hall effect, the spin current along $z$ can produce a transverse voltage difference $\Delta V_y$ that also varies as $\sinh(x/\lambda)$. This is consistent with experiments if the longest $\lambda$ is comparable to or larger than the sample length $L$, and the shorter $\lambda$‘s are smaller than the separation between the input or output lead and the nearest voltage probe. In this model even seemingly linear voltage profiles are due to a surface mode.

I. INTRODUCTION

In principle, a thermal gradient $\nabla T$ can produce a spin current. This magnetic analog of the Seebeck effect, whereby electric currents are generated by $\nabla T$, is known as the spin-Seebeck effect (SSE). Evidence for the spin-Seebeck effect has recently been observed in ferromagnet films, with thicknesses $d_f \sim 10$ nm along $z$ and lengths $L \sim 10$ mm along $x$, grown on insulating substrates. When subjected to a temperature difference across $x$ (see Fig. 1a), a nonzero voltage difference $\Delta V_y$ across the width of the sample is observed; this signal is attributed to an Inverse Spin Hall Effect (ISHE) due to an inferred spin-Seebeck-induced potential gradient along $z$. (We employ the magnetoelectrochemical potential $\mu_{\uparrow,\downarrow}$ introduced in Ref. 1, and defined in Sec. VI.) The magnitude of $\Delta V_y$ is observed to decay in space (along $x$) over a length much greater than a spin-diffusion length.

The relation between the applied temperature difference and the measured voltage difference is complicated; the connection is represented by

$$\Delta T_x \xrightarrow{\text{Equil}} \partial_x T \xrightarrow{\text{SSE}} \partial_z \mu_{\uparrow,\downarrow} \xrightarrow{\text{ISHE}} \Delta V_y, \tag{1}$$

where $\Delta T_x$ is applied and $\Delta V_y$ is measured, and “Equil.” denotes thermal equilibration processes. The present work shows the details of $\Delta T_x \xrightarrow{\text{Equil}} \partial_x T$, and then discusses $\partial_x T \xrightarrow{\text{SSE}} \partial_z \mu_{\uparrow,\downarrow}$ and $\partial_z \mu_{\uparrow,\downarrow} \xrightarrow{\text{ISHE}} \Delta V_y$.

**Experiments.** The voltage is measured in one of two ways: (a) by depositing narrow ($\sim 10$ nm along $x$) wires on top of the sample that cross the width (from $y = -w/2$ to $y = w/2$); or (b) by attaching point contacts on top of the sample at both edges across the width (at $y = -w/2$ and $y = w/2$). In both cases, several (wire or point) contacts are deposited at intervals along the length $x$ (note that each of Figs. 1a and 1b shows only one such contact), the voltage difference $\Delta V_y$ is measured across $y$, and determined as a function of $x$. Each of Refs. 2–5 measure the SSE using Pt wires, and Ref. 2 measures the SSE using point contacts. (Ref. 5 also employs point contacts, but its SSE signal is small enough to be ambiguous.) It has been found that the SSE is not measured when Cu wires are used instead of Pt; this is attributed to the weakness of the spin-orbit interaction in Cu. Because the geometry is simpler, the present work considers the effect for point contacts.

Reference 2 observes the voltage difference $\Delta V_y$ along $y$ to have a $\sinh(x/\lambda)$-like form along the sample for some $\lambda = \lambda_{\text{expt}}$, thus indicating a surface effect associated with heat input and output. It has been suggested that this surface effect is governed by magnon-phonon thermal equilibration within the sample, which has a characteristic length of $\lambda_{\text{mp}}$. However, Ref. 6 estimates that for permalloy (Ni$_{81}$Fe$_{19}$) this equilibration should yield a maximum characteristic length of only $\lambda_{\text{mp}} = 0.3$ mm, whereas experiment shows the spin-Seebeck effect to have a characteristic length at least an order of magnitude larger.

An additional puzzling aspect of the experiments (partially responsible for the recent flurry of interest in them) is that scratching off the center of the sample, to leave a region only of substrate – which cannot carry spin current – has no measurable effect on $\Delta V_y$. However, it should be kept in mind that the spin current, unlike the electric current, is not associated with a strictly
two-subsystem approach of Ref. 7. We first consider a model 1D system with three sub-systems: sample phonons (designated by subscript p), sample magnons (m), and substrate phonons (s). In addition to various geometrical lengths, there are three different lengths associated with Fig. 1: the sample magnon-phonon equilibration length \( \lambda_{mp} \); the substrate-sample phonon equilibration length \( \lambda_{ps} \); and an infinite length that leads to the usual linear thermal profile. Recall that Ref. 2 observes a sinh \((x/\lambda)\) profile of the effect. If \( \lambda \ll L \), then sinh \((x/\lambda)\) can decay too close to the boundaries to be experimentally observed. Conversely, if \( \lambda \gg L \), then sinh \((x/\lambda)\) will appear to be linear in \( x \), which may explain the linear signal observed by Refs. 3 and 4. It is therefore likely that the longer of \( \lambda_{ps} \) and \( \lambda_{mp} \) is the decay length observed for \( \Delta V_y \). Moreover, because the results are independent of \( \ell_d \), we expect that the longer of the two characteristic mode lengths \( \lambda_{long} \gg \ell_d \) and the shorter characteristic mode length \( \lambda_{short} \ll \ell_d \).

When both magnon-phonon equilibration (internal to the ferromagnetic sample, and not present for a non-magnetic sample) and sample-substrate equilibration (not present for a sample with no substrate, as considered by Ref. 7) are present, the coupling between these two modes further separates their characteristic lengths. That is, \( \lambda_{long} \) and \( \lambda_{short} \) are respectively greater and less than both \( \lambda_{ps} \) and \( \lambda_{mp} \). Although we find that coupling increases the longer mode length, we do not otherwise intend to explain the very long experimental decay length \( \lambda_{expt} \). Rather, we show how the applied longitudinal temperature difference leads, via transverse out-of-plane thermal gradients and spin currents, to the transverse in-plane voltage difference. A theoretical estimation of \( \lambda_{mp} \) on the order of \( \lambda_{expt} \) remains to be made.

Since we show that the length enhancement from mode coupling is not enough for the \( \lambda_{expt} \) estimated by Ref. 6 to match \( \lambda_{expt} \) (for permalloy), the present work highlights the need for a revisiting of that theory. For example, it has recently been proposed\(^9,10\) that electron-phonon drag and magnon-phonon drag processes are important in explaining Refs. 2–4. (The kinetic theory of electron-phonon drag is found, for example, in Refs. 11, 12, and 13.) Neither Ref. 6 nor the present work considers such effects.

**Heat Flow in 2D.** As argued above, the fluxes and thermodynamic gradients along \( z \) (rather than along \( x \)) are responsible for \( \Delta V_y \). Thus we analyze a 2D system, with heat flow along both \( x \) and \( z \) and translational symmetry along \( y \). In contrast to the 1D model, in 2D when one accounts for two thermal subsystems (\( p \) and \( m \)) sharing a volume and the third (\( s \)) sharing a surface with the other two, one finds an infinite number of modes and their associated lengths. All but the modes with the two longest lengths are due to the system geometry, and the temperatures and thermal gradients along \( z \) vary as sinh \((x/\lambda)\). By the SSE, these thermal gradients generate up- and down- spin carrier currents that also vary as sinh \((x/\lambda)\). Then, due to the ISHE, the spin current

**FIG. 1.** The substrate (s, dark gray) and ferromagnetic sample (F, light gray) of the spin-Seebeck experiment. Here, (a) shows the typical experimental system, and (b) shows the system with a disconnection (scratch) in the sample (but not the substrate), of length \( \ell_d \). An external magnetic field \( B_z \) is applied along \( z \), and a temperature difference \( \Delta T_z \) along \( x \) is maintained by a heater and a heat sink. A voltage difference \( \Delta V_y \) is deposited on the sample.

**1D Model of Heat Flow.** This work studies temperature and heat flow in this system. We employ irreversible thermodynamics to justify and extend the 1D, irreversible thermodynamics to justify and extend the 1D.
along \( z \) (of spins pointing along \( x \) due to the applied magnetic field) produces the voltage \( \Delta V_y \) that also varies as \( \sinh (x/\lambda) \).

Within the context of the present work, whose physical basis is the suggested mechanisms of Ref. 3, \( \Delta V_y \) can only be associated with an exponential form; there will be no spin current along \( z \) due to a truly linear temperature profile. If this set of mechanisms explains the data, then the linear profile observed by Refs. 3 and 4 must be due to a decay length much larger than the sample length, that is, \( \lambda \gg L \). (Further, smaller mode lengths must be shorter than the distance between the input and output leads and the nearest voltage probe.)

**Outline.** Section II employs irreversible thermodynamics to find the energy transferred between two systems at different temperatures, specifically considering systems that share a surface (e.g., the sample and substrate) and systems that share a volume (e.g., magnons and phonons in the ferromagnet). Section III finds the characteristic lengths of the thermal equilibration modes for the 1D model, and finds the spatial profiles of the phonon and magnon temperatures and heat fluxes. For 2D heat flow, Sec. IV finds the shape of the spatial profile of temperatures and heat fluxes, and numerically solves for the characteristic lengths and \( z \)-dependence of the phonon and magnon heat flux magnitudes. Section V compares estimates of the thermal equilibration lengths\(^8\) to the observed decay length of \( \Delta V_y \). Section VI discusses the connection between the thermal gradients found in Sec. IV and the magnetoelectrochemical potentials (which involves the spin-Seebeck effect) and the subsequent connection to \( \Delta V_y \) (which involves the inverse Spin Hall effect). Section VII provides a brief summary and conclusion. Appendix A gives details of the bulk and conclusion. Appendix A gives details of the bulk and conclusion. Appendix A gives details of the bulk and conclusion.

**II. THERMODYNAMICS**

Flow described by thermodynamics is properly given by the methods of irreversible thermodynamics. We present here a derivation of a result central to Ref. 7, which is the basis of Ref. 6, but which is simply written in Ref. 14.

**A. General Equilibration of Two Systems**

We consider any two systems through which heat and entropy (but not matter, quasi-momentum, or momentum) flow. We later specifically consider energy equilibration between the phonon-magnon subsystems in a ferromagnet (as in Refs. 6 and 7), as well as energy equilibration between the respective phonon systems of a ferromagnet and a non-magnetic insulator in contact.

In two such systems, designated \( \alpha \) and \( \beta \), the energy differentials may be written as

\[
dE_\alpha = T_\alpha dS_\alpha, \quad dE_\beta = T_\beta dS_\beta,
\]

where \( T \) is the temperature and \( S \) is the entropy. By energy conservation \( dE_\alpha = -dE_\beta \), so

\[
dS_\alpha = \frac{dE_\alpha}{T_\alpha}, \quad dS_\beta = -\frac{dE_\alpha}{T_\beta}.
\]

Since the entropy change must be non-negative,\(^{15} \) we have

\[
0 \leq \dot{S}_\alpha + \dot{S}_\beta = \left( \frac{1}{T_\alpha} - \frac{1}{T_\beta} \right) \dot{E}_\alpha = \left( \frac{T_\beta - T_\alpha}{T_\alpha T_\beta} \right) \dot{E}_\alpha.
\]

For \( \dot{S}_\alpha + \dot{S}_\beta \geq 0 \) to hold we must have

\[
\dot{E}_\alpha = \zeta (T_\beta - T_\alpha),
\]

where \( \zeta > 0 \). That is, by irreversible thermodynamics, the energy flux is driven by a difference in intensive thermodynamic quantities. The proportionality coefficient \( \zeta \) has units of a specific heat divided by time, and as noted below depends either on a boundary conductance (for systems that share a common surface) or a relaxation time (for systems that share the same volume).

Specific heats per unit volume (\( C \)) are defined via

\[
\dot{E}_\alpha = C_\alpha \dot{S}_\alpha, \quad \dot{E}_\beta = C_\beta \dot{S}_\beta,
\]

where \( \varepsilon = E/V \) and \( V \) is the volume of the system. Use of Eqs. (5) and (6), and \( \dot{E}_\beta = -\dot{E}_\alpha \), yields

\[
\dot{T}_\alpha = \frac{T_\beta - T_\alpha}{\tau_\alpha}, \quad \dot{T}_\beta = \frac{T_\alpha - T_\beta}{\tau_\beta},
\]

where \( \tau_\alpha \equiv C_\alpha V_\alpha/\zeta \) and \( \tau_\beta \equiv C_\beta V_\beta/\zeta \) have units of time. Then

\[
\Delta \dot{T}_\alpha = \dot{T}_\beta - \dot{T}_\alpha = -\frac{T_\beta - T_\alpha}{\tau_\alpha + \tau_\beta},
\]

where we define

\[
\tau_{\alpha\beta} \equiv \frac{\tau_\alpha \tau_\beta}{\tau_\alpha + \tau_\beta}.
\]

Equation (8) justifies Eq. (1) of Ref. 7.

**B. Two Systems Occupying the Same Volume**

Energy conservation in two systems that occupy the same volume \( V \) (e.g., the phonon and magnon systems within a ferromagnet) gives \( \dot{E}_\alpha = -\dot{E}_\beta \), so that substitution of Eqs. (7) and (5) into Eq. (6) yields

\[
\frac{C_\alpha}{\tau_\alpha} = \frac{C_\beta}{\tau_\beta} = \frac{\zeta}{V}.
\]

Then, with \( \tau_\beta = (C_\beta/C_\alpha) \tau_\alpha \), equation (9) gives

\[
\frac{C_\alpha}{\tau_\alpha} = \frac{C_\beta}{\tau_\beta} = \left( \frac{C_\alpha C_\beta}{C_\alpha + C_\beta} \right)^{-1} \tau_{\alpha\beta}^{-1}.
\]

This is the case studied by Ref. 7.
tution of Eqs. (12) and (7) into Eq. (6) gives

Here $h$ that phonon systems in Fig. 1), we write $A$ in Section IV. We now consider a model in which heat flows only in the $yz$-plane; this restriction is lifted in Section IV.

C. Two Systems with a Contact Surface

For two systems in thermal contact over a surface of area $A$ (e.g., the ferromagnet and substrate’s respective phonon systems in Fig. 1), we write $\zeta = h_K A^{16,17}$ so that

$$\dot{E}_\alpha = - \dot{E}_\beta = h_K A (T_\beta - T_\alpha).$$

(12)

Here $h_K$ is the thermal boundary conductance. Substitution of Eqs. (12) and (7) into Eq. (6) gives

$$\tau_\alpha = \frac{d_\alpha C_\alpha}{h_K}, \quad \tau_\beta = \frac{d_\beta C_\beta}{h_K},$$

(13)

where $d$ is the thickness of the material in the direction normal to the contact surface. Eq. (9) then gives

$$\tau_{\alpha \beta} = h_K \left( \frac{d_\alpha C_\alpha d_\beta C_\beta}{d_\alpha C_\alpha + d_\beta C_\beta} \right).$$

(14)

III. MODEL FOR HEAT FLOW IN 1D

The experiments have a ferromagnet/substrate system where a thermal gradient is applied by a heater at $x = -L/2$ and a heat sink at $x = L/2$ (see Figure 2). For sample isolation, we take them to be in contact only with the substrate. This affects the relative amplitudes of temperature and thermal flux in each mode, but does not change the mode lengths.

We now consider a model in which heat flows only along the length of the materials (the $x$-direction in Figs. 1 and 2), i.e., heat flow in each system is uniform in the $yz$-plane (Sect IV considers flow along $x$ and $z$). Conservation of energy, with an energy source, is given by

$$\dot{\varepsilon} + \partial_x j^\varepsilon_x = S^\varepsilon,$$

(15)

where $j^\varepsilon$ is the energy (and heat) flux, and $S^\varepsilon$ represents the rate of heat transfer per unit volume from one system or subsystem to another. We consider steady state solutions, so that $\dot{\varepsilon} = 0$. Further, we take the magnon system ($m$) in the ferromagnet to only transfer energy to/from the phonon system ($p$) in the ferromagnet. Similarly we take the substrate ($s$) to only transfer energy to/from the phonon system ($p$) in the ferromagnet, thereby neglecting direct magnon-substrate coupling.

The rate of energy transfer per volume ($V = Ad$) between substrate phonons and sample phonons (an energy source $S$) is found from Eq. (12) as

$$S^\varepsilon_{s \rightarrow p} = \frac{h_K}{d_F} (T_s - T_p), \quad S^\varepsilon_{p \rightarrow s} = \frac{h_K}{d_s} (T_p - T_s).$$

(16)

Here $S^\varepsilon_{A \rightarrow B}$ is the volume rate of energy transfer from system $A$ to system $B$. This energy transfer is in the form of a source only because here we take the heat flux to be only along $x$; this is a (non-physical) consequence of making such a 1D model. When we include heat flow also along $z$ in Sec. IV, the substrate-sample phonon energy transfer is properly treated as a heat flux along $z$.

The volume rate of energy transfer between the magnons and phonons in the sample is found by substitution of Eqs. (7) and (10) into Eq. (6), which gives

$$S^\varepsilon_{m \rightarrow p} = - S^\varepsilon_{p \rightarrow m} = \frac{C_m}{\tau_m} (T_m - T_p).$$

(17)

Here we have used Eq. (10) to replace $C_p/\tau_p$ with $C_m/\tau_m$. Applied in turn to the substrate, magnons, and phonons, Eq. (15) gives

$$\partial_x j^\varepsilon_x = \frac{h_K}{d_F} (T_p - T_s),$$

(18)

$$\partial_x j^\varepsilon_m = - \frac{C_m}{\tau_m} (T_m - T_p),$$

(19)

$$\partial_x j^\varepsilon_p = \frac{h_K}{d_F} (T_s - T_p) + \frac{C_m}{\tau_m} (T_m - T_p).$$

(20)

As usual, for each subsystem we take the heat flux to be proportional to the gradient of temperature,$^{1,15,18}$ so

$$j^\varepsilon_x = - \kappa \partial_x T.$$  

(21)

Here $\kappa > 0$, i.e., heat flows from hot to cold. We have neglected cross-terms in Eq. (21), where gradients of other intensive thermodynamic quantities also cause a flux; we discuss these cross-terms in further detail in Sec. VI. Substitution of Eqs. (18), (19), and (20) into the linearized gradient of Eq. (21) in turn gives

$$- \left( \frac{d_\alpha \kappa_\alpha}{h_K} \right) \partial_x^2 T_s = T_p - T_s,$$

(22)

$$- \left( \frac{C_m \tau_m}{\kappa_m} \right) \partial_x^2 T_m = T_p - T_m,$$

(23)

$$- \kappa_p \partial_x^2 T_p = - \frac{h_K}{d_F} (T_p - T_s) - \frac{C_m}{\tau_m} (T_p - T_m).$$

(24)
A. Characteristic Lengths

We denote the inhomogeneous parts of $T_s$, $T_p$, and $T_m$ with primes. They all vary as $e^{\pm q^2}$, so the characteristic length is $\lambda = q^{-1}$. Then, solving Eqs. (22) and (23) for $T_s'$ and $T_m'$ yields

$$T_s' = \frac{T_p'}{1 - \left(\frac{d_s \kappa_s}{h \kappa_K}\right) q^2}, \quad T_m' = \frac{T_p'}{1 - \left(\frac{\kappa_m \tau_m}{C_m}\right) q^2}. \quad (25)$$

Substitution of Eq. (25) into Eq. (24) gives

$$-\kappa_p q^2 = \frac{h \kappa}{d_F} \left(1 - \frac{\kappa_m \tau_m}{h \kappa_K} q^2\right) + \frac{C_m}{\tau_m} \left(1 - \frac{\kappa_m \tau_m}{C_m} q^2\right).$$

(26)

This is cubic in $q^2$. One solution is $q^2 = \lambda^{-2} = 0$, corresponding to the usual linear temperature profile, for which $T_s' = T_p' = T_m'$.

We define the inverse lengths $q_{mp} = \lambda_{mp}^{-1}$ and $q_{ps} = \lambda_{ps}^{-1}$; the former associated with magnon-phonon equilibration within the ferromagnet and the latter associated with substrate-sample phonon equilibration. They satisfy

$$q_{mp}^2 \equiv \frac{C_m}{\tau_m} \left(\frac{\kappa_m + \kappa_p}{\kappa_m \kappa_p}\right), \quad q_{ps}^2 \equiv \frac{h \kappa}{d_F} \left(\frac{d_s \kappa_s}{d_F \kappa_p + d_s \kappa_s}\right).$$

(27)

They are the inverse lengths of the modes when the magnon-phonon system and the substrate-sample phonon system do not interact. We also define the dimensionless ratios

$$\Gamma_{mp} \equiv \left(\frac{\kappa_m}{\kappa_m + \kappa_p}\right), \quad \Gamma_{ps} \equiv \left(\frac{d_s \kappa_s}{d_s \kappa_s + d_s \kappa_s}\right).$$

(28)

and let $\Gamma = \Gamma_{mp} \Gamma_{ps}$. Then for $q^2 \neq 0$, equation (26) can be written as

$$0 = q^4 - q^2 \left(q_{mp}^2 + q_{ps}^2\right) + \left(q_{mp}^2 q_{ps}^2 - q_{mp} q_{ps}^2 \Gamma\right).$$

(29)

The solutions are

$$q_{(long,short)}^2 = \frac{q_{mp}^2 + q_{ps}^2}{2} \pm \sqrt{\left(\frac{q_{mp}^2 - q_{ps}^2}{2}\right)^2 + q_{mp} q_{ps}^2 \Gamma},$$

(30)

where $q_{long}$ is associated with the minus sign, so that $q_{long} < q_{short}$ and $\lambda_{long} > \lambda_{short}$.

We now consider two extreme cases. If there is no substrate (or if $h \kappa \to 0$), then

$$|q| \to q_{mp} = \sqrt{\frac{C_m}{\tau_m} \left(\frac{\kappa_p + \kappa_m}{\kappa_m \kappa_p}\right)},$$

(31)

which on use of Eq. (11) reproduces the result of Ref. 7 (which employs $A$ for $q$). If there is a substrate but no
The total heat flux in the ferromagnet as
\[
T_p = T_0 + \alpha x + \sum_{\gamma=1}^{2} \left[ T_\gamma^a \sinh (q_\gamma x) + T_\gamma^b \cosh (q_\gamma x) \right],
\]
(33)
where \(T_0, T_1^a, T_2^a, T_1^b, T_2^b\) are temperatures, and \(\alpha\) is a temperature gradient. The temperatures \(T_{(1,2)}^a\) and \(T_{(1,2)}^b\) are found by application of the boundary conditions on the heat currents, which are proportional to \(\partial_x T_{(p,m,s)}\), with \(T_1^a = 0 = T_2^a\) if the heat fluxes have symmetric boundary conditions.

Recall that \(T = T_0 + \alpha x\) for an isolated system under an applied temperature gradient.

Using Eq. (27), substitution of Eq. (33) into Eq. (25) (which applies only to the inhomogeneous parts of \(T_{(s,p,m)}\)) gives, with no new parameters,
\[
T_s = T_0 + \alpha x + \sum_{\gamma=1}^{2} \left[ \frac{q_{ps}^2}{q_{ps}^2 - \frac{d_\gamma \kappa_d + d_F \kappa_p}{d_F \kappa_p}} q_\gamma^2 \right] \times \left[ T_\gamma^a \sinh (q_\gamma x) + T_\gamma^b \cosh (q_\gamma x) \right],
\]
(34)
\[
T_m = T_0 + \alpha x + \sum_{\gamma=1}^{2} \left[ \frac{q_{mp}^2}{q_{mp}^2 - \frac{\kappa_m + \kappa_p}{\kappa_p}} q_\gamma^2 \right] \times \left[ T_\gamma^a \sinh (q_\gamma x) + T_\gamma^b \cosh (q_\gamma x) \right].
\]
(35)
Substituting Eqs. (33), (34) and (35) into Eq. (21) in turn gives the heat current in each subsystem:
\[
j(x) = \sum_{\gamma=1}^{2} q_\gamma \left[ T_\gamma^a \cosh (q_\gamma x) + T_\gamma^b \sinh (q_\gamma x) \right],
\]
(36)
\[
j^{e,(s,p)} = -\kappa_p \alpha - \kappa_p \sum_{\gamma=1}^{2} q_\gamma \left[ T_\gamma^a \cosh (q_\gamma x) + T_\gamma^b \sinh (q_\gamma x) \right],
\]
(37)
\[
j^{e,m} = -\kappa_m \alpha - \kappa_m \sum_{\gamma=1}^{2} q_\gamma \left[ T_\gamma^a \cosh (q_\gamma x) + T_\gamma^b \sinh (q_\gamma x) \right] \times \left[ T_\gamma^a \cosh (q_\gamma x) + T_\gamma^b \sinh (q_\gamma x) \right],
\]
(38)
The total heat flux in the ferromagnet \(j_{x}^{\text{fp}} = j_{x}^{e,p} + j_{x}^{e,m}\) is
\[
\]
(39)
The boundary conditions on \(j_{x}^{(e,p,m)}\) at \(x = -L/2\) and \(x = L/2\) give \(\alpha, T_{(1,2)}^a\) and \(T_{(1,2)}^b\).

Because heat flux is continuous, the total heat flux (integrated over all subsystems) due to each surface mode must be zero. This condition is satisfied by Eqs. (36), (37), and (38) on substitution from Eqs. (27) and (30).

There are five unknowns in Eqs. (36), (37), and (38) \((\alpha, T_1^a, T_2^a, T_1^b, T_2^b)\), and seemingly six boundary conditions (for each of the three fluxes, one at \(x = -L/2\) and one at \(x = L/2\)). However, because the total energy flux is conserved (i.e., no losses at the top of the ferromagnet \(d_F\) or at the bottom of the substrate \(−d_s\) in Fig. 1), there are only five independent conditions.
For comparison to the theory of Ref. 7, we now consider the bulk system if the heaters contact the sample and there is no substrate (so that \( q^2 = q_{mp}^2 \) and \( q_1^2 = 0 = q_{ps}^2 \)). Then \( j_x^F \rightarrow - (\kappa_p + \kappa_m) \alpha \), which reproduces the homogeneous result of Ref. 7 (where \( Q \equiv j_x^F \)), and satisfies the condition of zero total heat flux due to the surface mode. If the heaters directly transfer energy only to and from phonons (so that heat flow in the magnon system vanishes at \( x = L/2 \) and \( x = -L/2 \)), then \( T_2 \rightarrow \kappa_m \alpha / [q_{mp} \kappa_p \cosh (q_{mp} L/2)] \) and \( T_2^b \rightarrow 0 \), which reproduces the inhomogeneous solution of Ref. 7. As noted above, because \( T_{(1,2)}^b \) are associated with a term proportional to \( \sin (q_{(1,2)} x) \) in the heat flux, then \( T_1^b = 0 = T_2^b \) for boundary conditions on the heat fluxes (i.e., the same heat current is injected into each system at the “hot” side as is withdrawn from each system at the “cold” side).

IV. HEAT FLOW IN 2D

We now consider heat flux along \( z \), to explicitly permit heat transfer between the substrate and the sample. We first detail the analytic theory, then present its numerical solution.

A. Analytic Results

To completely describe the \( z \)-dependence of the temperatures and heat fluxes in the system, the \( z \)-dependence of the heat flux input by the heater at \( x = -L/2 \) must be considered. In principle, it may have any functional form, and therefore properly requires a Fourier series in \( \sin (k z) \) and \( \cos (k z) \) that includes an infinite number of lengths \( k^{-1} \) associated with the \( z \)-direction. However, if the thickness (along \( z \)) of the substrate is much smaller than its length (along \( x \)), then \( k^{-1} \) should be very small compared to \( \lambda_{(long\,short)} = \lambda_{(long\,short)} \) of Eq. (30). The contributions from this \( z \)-dependence should decay along \( x \) over a distance on the order of the non-uniformity along \( z \), and therefore we do not explicitly include them in the analytic theory. The cost of neglecting these high \( k \) values is that we cannot specify a heat input with a complicated variation along the thickness.

We thus generalize equations (33)-(35) to take the form

\[
T_{(s,p,m)}(x,z) = T_{0(s,p,m)} + \alpha_{(s,p,m)} x
+ \sum_{n=1}^{N} \left[ T_n^{a(s,p,m)} (z) \sinh (q_n x) + T_n^{b(s,p,m)} (z) \cosh (q_n x) \right].
\]  

(40)

We permit there to be \( N \) surface modes; for heat flow along only \( x \), the one-dimensional heat equations guarantee that \( N = 2 \), but the two-dimensional equations are nonlinear so that any \( N \) is allowed.

We take symmetric boundary conditions on heat flux along \( x \) so that \( T_{(s,p,m)}^b(z) = 0 \). Then, substitution of Eq. (40) into Eq. (21) gives the heat fluxes along \( x \) and \( z \) to be

\[
j_x^{(s,p,m)} = - \kappa_{(s,p,m)} q_n \sinh (q_n x), \quad j_z^{(s,p,m)} = - \kappa_{(s,p,m)} q_n \cosh (q_n x).
\]  

(41)

(42)

This section derives the functional forms of \( T_{(s,p,m)}(z) \) and finds their amplitudes for example material parameters. It also discusses the bulk and boundary conditions that permit determination of their amplitudes, with the details of these conditions given by Appendix A.

On properly treating the heat transfer between sample phonons and substrate phonons as \( z \)-directional currents, employing Eqs. (21) and (15) gives

\[
\partial_x T_s = 0, \quad \partial_z T_s = 0, \quad \partial_x T_m = -C_m / \tau_m (T_m - T_p), \quad \partial_z T_m = -C_m / \tau_m (T_m - T_p).
\]  

(43)

(44)

(45)

These equations give

\[
T_0 = T_{0s} = T_0, \quad \alpha_m = \alpha_p = \alpha,
\]  

(46)

but they do not explicitly impose any conditions on \( T_0 \) or \( \alpha_s \). For steady-state flow, however, we must take

\[
T_{0s} = T_0, \quad \alpha_s = \alpha.
\]  

(47)

This relation guarantees that for any two of \( \kappa_{(s,p,m)} \) to go continuously to zero, we recover the expected \( j_x^s \rightarrow -\kappa \alpha \).

We now find \( T_{(s,p,m)}(z) \) by substituting Eq. (40) into Eq. (43) and the decoupled forms of Eqs. (44) and (45). Substitution of Eq. (40) into Eq. (43) gives

\[
\partial_z^2 T_s(z) = -q_n^2 T_s(z),
\]  

(48)

so that \( T_s(z) \) is sinusoidal:

\[
T_s(z) = A_s^{(1)} \cos (q_n z) + A_s^{(2)} \sin (q_n z).
\]  

(49)

Here, \( A_s^{(1)} \) and \( A_s^{(2)} \) are constants determined by conditions on heat flux (see Appendix A).

Decoupled equations for \( T_p \) and \( T_m \), and thus for \( T_{ps},(z) \) and \( T_{ms},(z) \), are found by combination of Eqs. (44) and (45). Addition and subtraction gives

\[
-\kappa_p \partial_x^2 T_p - \kappa_m \partial_z^2 T_m = 0,
\]  

(50)

\[
-\kappa_p \partial_x^2 T_p + \kappa_m \partial_z^2 T_m = 2 C_m / \tau_m (T_m - T_p).
\]  

(51)
Combination of Eqs. (50) and (51) gives
\[
\partial^2_q \partial^2_q T_p - q_{mp}^2 \partial^2_q T_p = 0, \tag{52}
\]
\[
\partial^2_q \partial^2_q T_m - q_{mp}^2 \partial^2_q T_m = 0, \tag{53}
\]
where we have employed Eq. (27). Use of Eq. (40) in Eqs. (52) and (53) gives, for each mode \( n \),
\[
\partial^2_q T_{(p,m)_n} (z) + q_n^2 T_{(p,m)_n} (z) + 2q_{mp}^2 \partial^2_q T_{(p,m)_n} (z) - q_{mp}^2 \partial^2_q T_{(p,m)_n} (z) = 0. \tag{54}
\]
The solution of Eq. (54) is
\[
T_{(p,m)_n} (z) = A^{(1)}_{(p,m)_n} e^{\sqrt{q_{mp}^2 - q_n^2} z} + A^{(2)}_{(p,m)_n} e^{-\sqrt{q_{mp}^2 - q_n^2} z} + A^{(3)}_{(p,m)_n} \cos (q_n z) + A^{(4)}_{(p,m)_n} \sin (q_n z). \tag{55}
\]
Here, \( A^{(1,2,3,4)}_{(p,m)_n} \) are constants determined by conditions on heat flux (see Appendix A).

Due to the mode splitting discussed in Sec. III, the 1D inverse lengths straddle \( q_{mp} \), that is, \( q_{\text{short}} \geq q_{mp} \geq q_{\text{long}} \).

Therefore, for \( \Gamma \neq 0 \), the exponential terms in Eq. (55) are, in fact, oscillating terms for each mode that has \( q_n \geq q_{\text{short}} \).

**B. Bulk and Boundary Conditions**

Although \( T_0, \alpha, A_n^{(1,2)} \), and \( A^{(1,2,3,4)}_{(p,m)_n} \) are \( 2 + 10N \) unknowns associated with the temperatures and heat fluxes, they are not free parameters. As shown in Appendix A, bulk energy conservation gives \( 4N \) conditions; energy conservation at the boundaries \( z = -d_s \) and \( z = d_F \), where we assume no heat loss to the vacuum, gives \( 3N \) conditions; there are \( 2N \) conditions on heat flux at the substrate-sample interface \( z = 0 \); and there are \( 2N \) conditions on temperature and heat flux near the boundaries \( x = \pm L/2 \). With these conditions, the present theory has no fitting parameters.

Specifically, the \( 3N \) boundary conditions at \( z = -d_s \) and \( z = d_F \) are given by
\[
j_{x}^{*} (x, z = d_F) = 0, \tag{56}
\]
\[
j_{x}^{*} (x, z = d_F) = 0, \tag{57}
\]
\[
j_{x}^{*} (x, z = -d_s) = 0. \tag{58}
\]
As discussed in Refs. 16–18, heat currents are driven across an interface by the temperature difference across the interface, so that
\[
j_{x}^{*} (x, z = 0) = -h_K [T_p (x, z = 0) - T_s (x, z = 0)]. \tag{59}
\]
which gives \( N \) conditions. At the interface we take heat to be transferred only between substrate and sample phonon systems, so that
\[
j_{x}^{*} (x, z = 0) = j_{x}^{*} (x, z = 0), \tag{60}
\]

or equivalently
\[
j_{x}^{*} (x, z = 0) = 0, \tag{61}
\]
giving another \( N \) conditions. One imposes any two of Eqs. (59), (60), and (61), with the third being implicitly guaranteed by energy conservation.

Only the remaining conditions, associated with the boundaries \( x = -L/2 \) and \( x = L/2 \), can be varied: the average temperature \( T_0 \), the temperature gradient \( \alpha \), and one condition for each of the \( N \) modes, associated with the relative amount of heat carried by each subsystem close to the heater. All of these \( 2 + N \) conditions are set by experiment, the first two of which are, respectively, proportional to the sum and difference of the heater and heat sink temperatures. The other \( N \) conditions are non-obvious, but Appendix A argues that they may be approximated by assuming that, near the heater, the heat flux carried along \( x \) by the substrate phonons dominates that carried by either the sample phonons or sample magnons.

**C. Numerical Solution**

One cannot assume that the inverse lengths for a 1D model for heat flow, given by Eq. (30) and now called \( q_{\text{long}}^{(1D)} \) and \( q_{\text{short}}^{(1D)} \), are equivalent to the inverse lengths associated with 2D flow. Indeed, numerical solution with each of \( q_{\text{long}}^{(1D)} \) or \( q_{\text{short}}^{(1D)} \) is inconsistent with energy conservation. Since the 2D heat flow equations are nonlinear, analytic solution is not possible in general. However, an iterative approach can be used to find consistent values for \( q \); solve the appropriate boundary conditions for the mode amplitude coefficients (i.e., the coefficients \( A_{(s,p,m)_n} \) in Eqs. (49) and (55)) using \( q_{\text{init}} = q_{\text{long}} \) or \( q_{\text{init}} = q_{\text{short}}^{(1D)} \), using these values for the coefficients, find the \( q_{\text{new}} \) that guarantees energy conservation; begin the loop again using an appropriately chosen \( q_{\text{init}} \) in between \( q_{\text{init}} \) and \( q_{\text{new}} \). One must iterate until \( q_{\text{new}} \) and \( q_{\text{init}} \) converge.

For our numerical calculations, we use the material parameters given in Table I. Note that Ref. 6 estimates \( \lambda_{mp} \) to be at least an order of magnitude too small to be the unusually large decay length of the observed voltage difference \( \Delta V_y \), and the present theory does not explain such a large discrepancy, because as shown in Fig. 3, we do not predict mode coupling to amplify the larger length by a full order of magnitude. This matter is discussed further below. For the numerical solution, we therefore estimate \( \lambda_{mp} = 2 \) mm from the observed voltage decay length in Fig. 2 of Ref. 2. We now present the results of this method, calculated using Mathematica v. 8.0.

Following Table I, Eq. (30) gives
\[
q_{\text{long}}^{(1D)} = 476.73 \text{ m}^{-1}, \quad q_{\text{short}}^{(1D)} = 1.0000 \times 10^6 \text{ m}^{-1}. \tag{62}
\]
TABLE I. Parameters used in numerical calculations, results of which are shown in Fig. 6. \(^{(b)}\)Taken from Fig. 3 of Ref. 10. \(^{(b)}\)To our knowledge, this has not been measured, so we make an order of magnitude estimation. \(^{(c)}\)Value unknown; \(\kappa_m/\kappa_p\) is likely to be lower at high temperature. \(^{(d)}\)Estimate from Fig. 2 of Ref. 2 for the decay length of the observed spin-Seebeck voltage signal. \(^{(e)}\)Estimate for Rh:Fe on Al\(_2\)O\(_3\) from Fig. 34 of Ref. 16.

Using these as trial values for the numerical solution of 2D heat flow boundary conditions, we find 2D inverse lengths consistent with energy conservation to be

\[
q_1^{(2D)} = 476.73 \text{ m}^{-1}, \quad q_2^{(2D)} = 1.0015 \times 10^6 \text{ m}^{-1}. \quad (63)
\]

Although \(q_{long}^{(1D)}\) and \(q_1^{(2D)}\) match to one part in \(10^8\) (not shown to this precision above), only \(q_1^{(2D)}\) satisfies energy conservation.

The subsystem contributions to heat flow along \(z\) and along \(x\) for the two modes associated with \(q_1^{(2D)}\) and \(q_2^{(2D)}\) are respectively shown in Figs. 4 and 5. Fig. 5 explains the significant difference between \(q_{short}^{(1D)}\) and \(q_2^{(2D)}\); the 1D solutions \(q_{long}^{(1D)}\) and \(q_{short}^{(1D)}\) should apply for heat flux along \(x\) uniform in \(z\). This holds for the \(q_1^{(2D)}\) mode in Fig. 5a, whereas the \(q_2^{(2D)}\) displays significant curvature in Fig. 5b.

**D. Infinite Number of Inverse Lengths**

Other consistent solutions \(q_{n \geq 2}^{(2D)} > q_2^{(2D)} > q_1^{(2D)}\) can be found numerically. We are here searching for the normal modes associated with heat flow with the largest decay lengths, the larger \(q\) (and therefore smaller \(\lambda\)) solutions are irrelevant to the current discussion. We do, however, discuss the nature of these solutions.

Figure 7 shows the magnitude of the seven smallest wavevectors (except \(q_1\)) versus the number of the solution \(n\) (numbered by magnitude with \(q_{n+1}^{(2D)} > q_n^{(2D)}\)). As \(n\) grows, the difference \(\delta q\) between the inverse lengths of successive modes approaches either \(\pi/d_s\) or \(\pi/(d_s + d_F)\); since \(d_s > d_F\), it is difficult to distinguish which is the limiting quantity. Thus, the higher solutions are associated with the geometry of the system. We do not discuss them further.

Note that this numerical method, which searches for consistent values of \(q\) by using trial values, might not obtain all solutions, no matter how exhaustive the list of trial values. However, any missed modes are expected to have large \(q\) and small \(\lambda\), and thus are irrelevant to the current discussion.

**V. ON THE MEASURED EXPONENTIAL LENGTH**

For the calculated maximum \(\lambda_{mp}\) of Ref. 6, the present theory cannot account for the anomalously large length (on the order of 1 mm) observed in the spin-Seebeck experiments. On one hand, for the sample-substrate length \(\lambda_{ps}\) to be on the order of 1 mm, with \(\kappa_s \approx \kappa_p \sim 10^2 \text{ W/m-K}\), \(d_s \sim 100 \text{ nm}\), and \(d_F \sim 10 \text{ nm}\), Eq. (27) gives an abnormally small thermal boundary conductance \(h_K \sim\)
FIG. 5. The phonon and magnon heat fluxes (in arbitrary units) along \( x \), for a given \( x \), as a function of \( z \), i.e., \(-\kappa s p m T^a_{s p m}(z)\), in the thermal equilibration modes with the two largest characteristic lengths. The substrate occupies \( z < 0 \) and the sample, with thickness magnified by \( 10^3 \), occupies \( z > 0 \). In (a), where \( n = 1 \), the magnon heat flux is multiplied by \( 10^{-3} \). For the parameters of Table I, (a) shows that along \( x \) the heat flow for \( n = 1 \) is carried by all three subsystems, with magnon heat flux opposing sample and substrate phonon heat flow, and (b) shows that along \( x \) the heat flux for \( n = 2 \) is carried mostly by the phonon subsystems, which oppose one another at the interface. In (b), where \( n = 2 \), the heat flux in the substrate has many oscillations because \( \lambda_{s p m}^{(D)} \ll d_s \). Although it is not obvious at this scale, each heat flux has some curvature.

1 W/m²-K. Although \( h_K \) is not known for the particular combinations of materials used in Refs. 2-4, Fig. 34 of Ref. 16 gives \( h_K \approx 10^7 \) W/m²-K (for Rh:Fe on Al₂O₃ at \( T = 50 \) K). We do not expect that thermal matching between substrate and sample in the spin-Seebeck experiments to be considerable worse. On the other hand, for the magnon-phonon length \( \lambda_{mp} \) to be on the order of 1 mm, the mode coupling term given by \( \Gamma_{mp} \) in Eq. (30) would have to account for a large increase of \( \lambda_{mp} \) (at least three-fold in the case of Permalloy). Because spin-Seebeck experiments are carried out near room temperature or at \( T \geq 40 \) K, it is unlikely that the magnons carry a significant amount of the heat flux in the ferromagnet, i.e., it is likely that \( \kappa_m \ll \kappa_p \). Since the mode coupling term \( \Gamma_{mp} \) is proportional to \( \kappa_m/\kappa_p \), mode coupling is likely a weak effect.

However, phonon-magnon drag, as proposed in Refs. 9 and 10, or some other mechanism may explain a much longer \( \lambda_{mp} \) than previously calculated, and \( \lambda_{mp} \) is further enhanced by the mode coupling found in Sec. III. Hence, for numerical calculations, we have taken \( \lambda_{mp} \) from experimental results, rather than from the theoretical estimate of Ref. 6 (see Table I). The results above show that, for such a large \( \lambda_{mp} \), in the spin-Seebeck system we expect a thermal gradient along \( z \) that varies as \( \sinh(x/\lambda) \), resembling the \( \Delta V_y \) measured by Ref. 2 (see its Fig. 2).

VI. RELATING LONGITUDINAL THERMAL GRADIENTS TO TRANSVERSE VOLTAGE DIFFERENCES

The relation between the applied longitudinal temperature gradient and the transverse voltage difference is complicated, and worth discussing. So far we have shown that the applied longitudinal temperature gradient leads to a transverse (along \( z \)) temperature gradient in the sample – the first of the three steps in Eq. (1), \( \Delta T_z \overset{\text{Equil}}{\rightarrow} \partial_z T \). In Sec. VIA we show how to go from this transverse temperature gradient to the accompanying transverse currents of the magneto-electrochemical potentials – the second of the three steps in Eq. (1), \( \partial_z T \overset{\text{SSE}}{\rightarrow} \partial_z \mu_{\uparrow,\downarrow} \) – which are defined below. Finally, in Sec. VI B we show how to go from these transverse gradients (along \( z \)) of the magneto-electrochemical potentials, via the up- and down- spin Hall conductivities, to the measured transverse (along \( y \)) voltage difference \( \Delta V_y \) – the third of the three steps in Eq. (1), \( \partial_y \mu_{\uparrow,\downarrow} \overset{\text{ISHE}}{\rightarrow} \Delta V_y \).

We do not consider the use of platinum bars, which introduces a very complex geometry and is beyond the scope of the present work (and, as noted above, the effect has been observed with point contacts).

A. On Magneto-electrochemical Potential, Temperature, and Spin Current

By irreversible thermodynamics, the total spin flux (defined below as the difference of the number fluxes of up- and down-spin carriers), is driven both by gradients of temperature and of magneto-electrochemical potentials. The magneto-electrochemical potentials are defined by

\[
\mu_{\uparrow,\downarrow} = \mu_{\uparrow,\downarrow}^1 - e\phi \pm \frac{g\mu_B}{2} \hat{H}^* \cdot \hat{M}.
\]

Here, \( \mu_{\uparrow} \) and \( \mu_{\downarrow} \) are the chemical potentials of up- and down-spin electrons, \( e \) is the electron charge, \( \phi \) is electrical potential, \( g \) is the electron g-factor, \( \mu_B \) is the Bohr magneton, \( \hat{H}^* \) is the effective magnetic field, and \( \hat{M} \) is the direction of magnetization. The field \( \hat{H}^* \) is the difference between external magnetic fields and the internal fields, including the exchange and dipole contributions, and is defined so that \( \hat{H}^* = 0 \) in equilibrium. A more detailed discussion of \( \hat{H}^* \) is given in Ref. 21.

The up- and down- spin fluxes are primarily driven by the respective gradients \( \mu_{\uparrow} \) and \( \mu_{\downarrow} \), but each has cross-terms associated with the other potential, as well
FIG. 6. The relative magnitudes of phonon and magnon heat flux along $z$ as a function of $x$ and $z$, i.e., $j_z^\varepsilon(x,y,m)$ in arbitrary units. The substrate (only part of which is pictured) is at $z < 0$ and the sample is at $z > 0$. The sample magnon heat flux is magnified here by the factor $3 \times 10^{11}$; for the parameter values of Table I, the sample is too thin for magnons to build up much heat flux along $z$. The profile of each subsystem’s heat flux along $z$ varies as $\sinh(qx)$.  

FIG. 7. The inverse lengths $q_n$ for $n = 2$ to $n = 7$, where the modes are numbered in order of increasing $q$ (or, equivalently, decreasing $\lambda = 1/q$). The inverse length $q_1$, which is not shown, is three orders of magnitude smaller than $q_2$. The difference $\delta q$ between the inverse lengths of successive modes quickly approaches a value near $\pi/d_s \approx \pi/(d_s + d_F)$, suggesting that the additional modes are associated with the physical geometry of the system.

as with the temperature. We thus write

\begin{align}
  j_\uparrow^z &= -L_\uparrow \varepsilon \partial_z T_m - \frac{\sigma_\uparrow}{e^2} \partial_z \bar{\mu}\uparrow - L_\uparrow \partial \bar{\mu}\downarrow, \\
  j_\downarrow^z &= -L_\downarrow \varepsilon \partial_z T_m - L_\downarrow \partial \bar{\mu}\downarrow - \frac{\sigma_\downarrow}{e^2} \partial_z \bar{\mu}\downarrow.
\end{align}

Here, $\sigma_\uparrow$ and $\sigma_\downarrow$ are the respective bulk conductivities of up- and down-spins (generally not equal in a ferromagnet), and $L_\uparrow$ and $L_\downarrow$ (with units of m/K-s) are cross-term coefficients associating thermal gradients and individual spin-carrier currents (thus associated with both the electrical and spin currents). By an Onsager relation\textsuperscript{22} $L_\uparrow\downarrow = L_\downarrow\uparrow$ (with units of m/J-s) are cross-term coefficients associating up and down spin currents with down and up magnetoelectrochemical gradients. Typically $L_\uparrow\downarrow = L_\downarrow\uparrow$ are taken to be small, so that the terms $L_\uparrow\downarrow \partial \bar{\mu}\downarrow$ and $L_\downarrow\uparrow \partial \bar{\mu}\downarrow$ are negligible.

To calculate $j_\uparrow^z$ and $j_\downarrow^z$ everywhere, we employ their boundary conditions (that they have zero normal component at each sample boundary, which assumes no surface scattering) and their bulk equations, given for steady state by

\begin{equation}
  \partial_z j_\uparrow^z = S_{\uparrow\downarrow}, \quad \partial_z j_\downarrow^z = S_{\downarrow\uparrow}.
\end{equation}

For charge conservation, the up- and down-spin source terms $S_{\uparrow\downarrow}$ and $S_{\downarrow\uparrow}$ (which are proportional to $(\bar{\mu}\uparrow - \bar{\mu}\downarrow)/\tau_{sf}$, where $\tau_{sf}$ is a characteristic spin-flip time\textsuperscript{18,21}) are equal and opposite. Substitution from Eqs. (65) and (66) into Eq. (67) gives two equations for two unknowns, $\bar{\mu}\uparrow$ and $\bar{\mu}\downarrow$. Because the temperatures are shown above to vary as $\sinh(x/\lambda)$, then $\bar{\mu}\uparrow$ and $\bar{\mu}\downarrow$ also vary as $\sinh(x/\lambda)$.

B. On the Spin Hall Effect

We now discuss how to go from $\partial_x \bar{\mu}\uparrow$ and $\partial_x \bar{\mu}\downarrow$ to the measured voltage difference along $y$, i.e., $\Delta V_y$. We work by analogy to the Hall effect, which occurs when an electric flux $\vec{J}$ is driven through a conductor in the presence of a magnetic field $\vec{B}'$ that is perpendicular to the current.
Consider a conductor of width \( w \) along \( y \). Let the electric current be driven along \( z \) by an applied electric field \( E_z \), so that charge carriers have a velocity \( v_z \). With an applied magnetic field \( (B'_y, 0, 0) \), a Lorentz force then drives the charge carriers along \( y \), so that charges of opposite signs accumulate at the edges. The Lorentz-force-induced current is given by \( J'_y = \sigma v_z B'_x \). In the steady state, there is no flow along \( y \), so an electric field \( E_y \) develops to oppose the Lorentz-induced current along \( y \).

The total charge flux along \( y \) is given by
\[
J_y = 0 = \sigma (E_y + v_z B'_x).
\]

The so-called Hall field \( E_y \) thus is given by
\[
E_y = -v_z B'_x = \frac{J_z B'_x}{ne},
\]
where we have used \( J = -nev \), and \( n \) and \( -e \) are the respective concentration and the charge of the charge carriers. The Hall voltage is \( \Delta V_y = E_y w \).

Thus, the Hall effect relates an applied electric current to a measured transverse electrical potential difference. In contrast, the Spin Hall effect (SHE) relates an applied electric current to transverse differences in the magnetoelectrochemical potentials, and the inverse Spin Hall effect (ISHE) relates an applied spin current to a transverse difference in electrical potential (see, for example, Refs. 23-28). For the SHE and ISHE there are fluxes of charge carriers with both up- and down- spin. Instead of the action of Lorentz force in the Hall effect, for the SHE there are forces due to the spin-orbit interaction, whose effect enters via zero up- and down-spin Hall conductivities \( \sigma_{H\uparrow} \) and \( \sigma_{H\downarrow} \). (Thus the effect of the spin-orbit interaction is taken to be a perturbation.) Instead of the electric field \( E_y = -\partial_y \phi \), the spin-orbit force is associated with \( -\partial_y \hat{\mu}_\uparrow \) and \( -\partial_y \hat{\mu}_\downarrow \). We take the contributions to the number fluxes along \( y \) of the up- and down-spin carriers by this spin-orbit force to be given by
\[
j^\uparrow_y = \frac{\sigma_{H\uparrow}}{e} \partial_y \hat{\mu}_\uparrow, \quad j^\downarrow_y = \frac{\sigma_{H\downarrow}}{e} \partial_y \hat{\mu}_\downarrow.
\]

The total number fluxes along \( y \) of the up- and down-spin carriers are thus written as
\[
j^\uparrow_y = -\frac{\sigma_{H\uparrow}}{e} \partial_y \hat{\mu}_\uparrow + \frac{\sigma_{H\downarrow}}{e} \partial_y \hat{\mu}_\downarrow, \quad j^\downarrow_y = -\frac{\sigma_{H\downarrow}}{e} \partial_y \hat{\mu}_\downarrow + \frac{\sigma_{H\uparrow}}{e} \partial_y \hat{\mu}_\uparrow.
\]

For no charge current along \( y \), the sum \( j^\uparrow_y + j^\downarrow_y = 0 \). We also assume no bulk spin current along \( y \), so \( j^\uparrow_y - j^\downarrow_y = 0 \). Thus, we take \( j^\uparrow_y = 0 \) and \( j^\downarrow_y = 0 \), so that Eqs. (71) and (72) give
\[
\partial_y \hat{\mu}_\uparrow = \frac{\sigma_{H\uparrow}}{\sigma_\uparrow} \partial_y \hat{\mu}_\uparrow, \quad \partial_y \hat{\mu}_\downarrow = \frac{\sigma_{H\downarrow}}{\sigma_\downarrow} \partial_y \hat{\mu}_\downarrow.
\]
The known sources \( \partial_y \hat{\mu}_\uparrow \) and \( \partial_y \hat{\mu}_\downarrow \) on the right-hand-sides (RHS) of Eq. (73) are uniform in \( y \).

To write the magnetoelectrochemical potential in terms of the concentrations of up- and down-spins and the electric potential, we linearize the chemical potentials and the effective magnetic field term as
\[
\delta \mu_{\uparrow,\downarrow} = \frac{\partial \mu_{\uparrow,\downarrow}}{\partial n_{\uparrow,\downarrow}} \delta n_{\uparrow,\downarrow}, \quad \delta \vec{H} \cdot \hat{M} = \frac{\mu_0 \mu_B}{\chi} (\delta n_\uparrow - \delta n_\downarrow),
\]
where \( \delta \) denotes deviations from equilibrium, \( \mu_0 \) is the permeability of free space, and \( \chi \) is the magnetic susceptibility. Then Eq. (64) gives
\[
\delta \mu_{\uparrow,\downarrow} = \frac{\partial \mu_{\uparrow,\downarrow}}{\partial n_{\uparrow,\downarrow}} \delta n_{\uparrow,\downarrow} - e \delta \phi \pm \frac{\mu_0 \mu_B^2}{2\chi}(\delta n_\uparrow - \delta n_\downarrow).
\]

With \( \partial \mu_{\uparrow,\downarrow}/\partial n_{\uparrow,\downarrow} \) uniform in \( y \), substitution of Eq. (75) into the left-hand-sides (LHS) of Eq. (73) gives
\[
\frac{\partial \mu_{\uparrow}}{\partial n_\uparrow} \partial_y \delta n_\uparrow - e \partial_y \delta \phi = \frac{\mu_0 \mu_B^2}{2\chi} (\delta n_\uparrow - \delta n_\downarrow) = \frac{\sigma_{H\uparrow}}{\sigma_\uparrow} \partial_z \hat{\mu}_\uparrow, \quad \frac{\partial \mu_{\downarrow}}{\partial n_\downarrow} \partial_y \delta n_\downarrow - e \partial_y \delta \phi = \frac{\mu_0 \mu_B^2}{2\chi} (\delta n_\uparrow - \delta n_\downarrow) = \frac{\sigma_{H\downarrow}}{\sigma_\downarrow} \partial_z \hat{\mu}_\downarrow.
\]

Since the RHS of Eqs. (76) and (77) known, they provide two equations for the three unknowns \( \delta n_\uparrow, \delta n_\downarrow, \) and \( \delta \phi \). A third relation is provided by Gauss’s Law:
\[
\partial_y^2 \delta \phi = -\frac{1}{\varepsilon_0 \varepsilon}(\delta n_\uparrow + \delta n_\downarrow),
\]
where \( \varepsilon_0 \) and \( \varepsilon \) are the permittivity of free space and the relative permittivity. Solving Eqs. (76)-(78) gives \( \delta n_\uparrow, \delta n_\downarrow, \) and \( \delta \phi \), the last of which is related to the measured voltage by \( \Delta V_y = \int_{-w/2}^{w/2} dy \delta \phi \). We now discuss the solution.

It is consistent to take \( \delta n_\uparrow = -\delta n_\downarrow \), i.e., local electroneutrality; Equations (76)-(78) then give that \( \partial_y \delta \phi \) and \( \partial_y \delta n_\uparrow \) are uniform in \( y \). Equations (76) and (77) can then be solved for \( \partial_y \delta n_\uparrow \) and \( \partial_y \delta \phi \). Defining the dimensionless ratio
\[
\eta = \frac{\partial \mu_{\uparrow} - \partial \mu_{\downarrow}}{\partial n_{\uparrow} - \partial n_{\downarrow}}, \quad \frac{2g_0 \mu_B^2}{\chi},
\]
we have
\[
\partial_y \delta n_\uparrow = \eta \left( \frac{\partial \mu_{\uparrow}}{\partial n_{\uparrow} - \partial n_{\downarrow}} \right)^{-1} \left( \frac{\sigma_{H\uparrow}}{\sigma_\uparrow} \partial_z \hat{\mu}_\uparrow - \frac{\sigma_{H\downarrow}}{\sigma_\downarrow} \partial_z \hat{\mu}_\downarrow \right),
\]

\[
\partial_y \delta \phi = -\left( \frac{1 - \eta}{2e} \right) \frac{\sigma_{H\uparrow}}{\sigma_\uparrow} \partial_z \hat{\mu}_\uparrow - \left( \frac{1 + \eta}{2e} \right) \frac{\sigma_{H\downarrow}}{\sigma_\downarrow} \partial_z \hat{\mu}_\downarrow.
\]
With $\Delta V_y = \int_{w/2}^{x/2} dy (\partial_y \delta \phi)$, integration of Eq. (81) over $y$ across the width of the sample then gives

$$\Delta V_y = \frac{w}{2e} \left[ (\eta - 1) \frac{\sigma_{\text{sh}}}{\sigma_+} \partial_y \vec{\mu}_\uparrow - (\eta + 1) \frac{\sigma_{\text{sh}}}{\sigma_-} \partial_y \vec{\mu}_\downarrow \right],$$

(82)

where we have employed the uniformity of $\partial_y \vec{\mu}_\uparrow$ and $\partial_y \vec{\mu}_\downarrow$ along $y$. As discussed above, $\vec{\mu}_\uparrow$ and $\vec{\mu}_\downarrow$ vary as $\sinh (x/\lambda)$, thus Eq. (82) predicts $\Delta V_y \sim \sinh (x/\lambda)$.

We emphasize that the $\Delta V_y$ predicted in the present work is entirely due to exponential modes generated at surfaces. If $\lambda \gg L$, then $\sinh (x/\lambda) \approx (x/\lambda)$. Therefore the present work is consistent with Refs. 3 and 4, which observe a linear $\Delta V_y$, if in these works the largest exponential length satisfies $\lambda \gg L$. To test this hypothesis, longer samples should be studied; the present work does not suggest how much longer.

Reference 32 analyzes the spin Hall effect in a spirit similar to that of the present work; it too neglects surface scattering. Surface scattering would make the present analysis more complex; see Landauer and Swanson for the effect of surface recombination on the ordinary Hall effect in semiconductors.

The present work shows that the relation between $\Delta V_y$ and $\Delta T_x$ is very complicated, and suggests that a direct relation $\Delta V_y \sim S_y \Delta T_x$ (see, e.g., Ref. 3) is correct, but may not be quantitatively useful. However, the present work does support such a qualitative analysis, where the applied thermal gradient along $x$ leads, via the spin-Seebeck effect, to spin carrier fluxes along $z$, which in turn produce the measured voltage difference $\Delta V_y$ along $y$.

### VII. SUMMARY AND CONCLUSION

The present work finds the detailed temperature profile for the spin-Seebeck system, including both sample and substrate, when a temperature difference $\Delta T_x$ is applied along $x$. For a 1D for heat flow (only along $x$) we find that the temperature contains a part varying as $\sinh (x/\lambda)$, for each of two characteristic lengths ($\lambda_{ps}$ and $\lambda_{ps}$), one of which may correspond to the observed decay length of $\Delta V_y$. Equations (30) and (27) show that doubling the thickness of both the sample and substrate should approximately double these lengths. Polishing (roughening) the substrate before depositing the sample should increase (decrease) $h_K$, and thus decrease (increase) $\lambda_{ps}$. If $\lambda_{ps}$ corresponds to the observed exponential decay length, measurements on a series of samples with increasingly rough sample/substrate interfaces should reveal this dependence. Further, changing the coupling factor between the modes (by changing $\kappa_m/\kappa_p$ or $d_s/\kappa_s/d_s/\kappa_p$) modifies both lengths – increasing either increases the larger length, which likely corresponds to the measured decay length of $\Delta V_y$.

For 2D heat flow (along both $x$ and $z$), we also find that the temperature and thermal gradients along $z$ in the spin-Seebeck system vary as $\sinh (x/\lambda)$, and find a complicated sinusoidal and exponential profile along $z$ for the thermal gradients, with an infinite number of characteristic lengths, which we study numerically. The longest of these corresponds to the longer length of the 1D model. The second longest length is a geometry-modified version of the shorter length of the 1D model. Further lengths are largely due to the geometry.

We show how the thermal gradient along $x$ leads to the measured $\Delta V_y$. The thermal gradient along $x$ leads to a thermal gradient along $z$, which then drives up- and down- spin currents along $z$ (the spin-Seebeck effect), and is accompanied by gradients along $z$ of the magnetoelectrochemical potentials. These magnetoelectrochemical potential gradients along $z$ then produce the measured $\Delta V_y$, via the inverse Spin Hall effect (due to a nonzero spin-orbit interaction that leads to spin-Hall conductivities). As discussed above, the exponential form of $\Delta V_y$ predicted by the current work is consistent both with $\Delta V_y \sim \sinh (x/\lambda)$ as observed by Ref. 2 and, for $\lambda > L$, with $\Delta V_y \sim x$, as observed in Refs. 3 and 4.

### VIII. ACKNOWLEDGEMENTS

We would like to acknowledge J. Sinova for informing us of the experiments, V. Pokrovsky for valuable conversations, and the support of the Department of Energy through grant DE-FG02-06ER46278.

Care must be taken in determining a new initial value for
the next iteration. For $q_{\text{init}}$ far from a consistent value (that
is, a value that satisfies energy conservation), then $q_{\text{init}}$ and $q_{\text{new}}$ will differ significantly. Naively choosing $q'_{\text{init}} = q_{\text{init}} + \frac{1}{2}(q_{\text{new}} - q_{\text{init}})$ can result in a non-converging series.

Appendix A: Bulk and Boundary Conditions for
Heat Flow along $x$ and $z$

With Eqs. (46) and (47) relating the linear terms in temperature, there are $2 + 10N$ unknowns in Eqs. (41), (42), (49) and (55): one $T_0$, one $\alpha$, and $10N$ amplitudes given by $A^{(1)}_m$, $A^{(2)}_m$, and $A^{(3)}_m$. This section details the bulk and boundary conditions on heat flux that give these unknowns.

1. Bulk Conditions

By matching coefficients of like terms, substitution of Eqs. (40) and (55) into Eq. (51) gives

$$A^{(1)}_m = -\frac{K_p}{\kappa_m} A^{(1)}_{pm}, \quad A^{(2)}_m = -\frac{K_p}{\kappa_m} A^{(2)}_{pm},$$

$$A^{(3)}_m = A^{(3)}_{pm}, \quad A^{(4)}_m = A^{(4)}_{pm}. \quad (A1)$$

Since each of the above relations is a single condition for each mode $n = 1, 2, ..., N$, then Eq. (A1) gives $4N$ conditions.
2. Boundary Conditions

a. Boundary Conditions on Heat Flux along $z$

There are a further $5N$ conditions given by the boundary conditions on the heat flux along $z$ for the various subsystems at $z = -d_s$, $z = 0$, and $z = d_F$. They are given above as Eqs. (56)-(58), and any two of Eqs. (59)-(61) with the third implicitly guaranteed by energy conservation.

b. Boundary Conditions on Heat Flux along $x$

Two further conditions that constrain the homogeneous temperature coefficients, $T_0$ and $\alpha$, come from the temperatures of the heater and the heat sink. The remaining conditions on heat flux along $x$ are not obvious.

With the heater and heat sink each in contact only with the substrate, we take the boundary conditions in the $x$-direction on each energy flux $j_x^s$ are symmetric (we employ this above in taking $T_{s.p.m}^b(z) = 0$). This precludes permitting the heat flux input by the heater to have a different profile in $z$ than the heat flux output to the heat sink. However, as stated above, we are only treating the region far enough away from the heaters that the details of heat flux entering and leaving at $x = \pm L/2$ are irrelevant. Only a full solution with an infinite sum over inverse lengths $q_n$ can treat the specifics of the interfacial input, and it is beyond the scope of this work to solve for infinite inverse lengths. Thus, we can not apply boundary conditions precisely at $x = \pm L/2$.

We make the following approximation: at $x = \pm L/2 \pm \ell_S$, where $\ell_S$ is just far enough away from the heater/heat sink that the details of the input heat flux are irrelevant, we take $\partial_x T_p = 0$ and $\partial_x T_m = 0$. We take the heaters to be in contact only with the substrate, and assume that a significant amount of heat does not seep into the sample over the distance $\ell_S$. Explicitly,

\[
\partial_x T_m(x = -L/2 + \ell_S) = 0, \quad (A2)
\]
\[
\partial_x T_p(x = -L/2 + \ell_S) = 0. \quad (A3)
\]

Recall that we take heat flux (and therefore $\partial_x T$) to be symmetric about $x = 0$, so that the conditions at $x = +L/2 - \ell_S$ are not independent. Although it is not obvious, Eqs. (A2) and (A3) give $N$ conditions, which relate the amplitudes of each of the $N$ surface modes to the others.

Thus, for the $2 + 10N$ unknowns in the substrate phonon, sample phonon, and sample magnon temperatures associated with heat flow along both $x$ and $z$, Eqs. (56)-(61) and (A1)-(A3) give $2 + 10N$ conditions, and there are no free parameters.
