(Dated: December 19, 2011)

Motivated by recent numerical studies of Ag on Pt(111), we derive an expression for the RKKY interaction mediated by surface states, considering the effect of anisotropy in the Fermi edge. Our analysis is based on a stationary phase approximation. The main contribution to the interaction comes from electrons whose Fermi velocity \(v_F\) is parallel to the vector \(R\) connecting the interacting adatoms; we show that in general, the corresponding Fermi wave-vector \(k_F\) is not parallel to \(R\). The interaction is oscillatory; the amplitude and wavelength of oscillations have angular dependence arising from the anisotropy of the surface state band structure. The wavelength, in particular, is determined by the projection of this \(k_F\) (corresponding to \(v_F\)) onto the direction of \(R\). Our analysis is easily generalized to other systems. For Ag on Pt(111), our results indicate that the RKKY interaction between pairs of adatoms should be nearly isotropic and so cannot account for the anisotropy found in the studies motivating our work. However, for metals with surface state dispersions similar to Be(10\bar{1}0), we show that the RKKY interaction should have considerable anisotropy.

I. INTRODUCTION

Surface reconstruction and self-assembly at interfaces have attracted considerable interest due to the desire to tailor electronic and other properties of semiconductor devices. Understanding the dominant interactions between atoms on surfaces is crucial for describing these larger-scale reconstruction processes. Classical models of surface stress, such as the Frenkel-Kontorova model,\textsuperscript{1,2} have been successful in describing many experimental systems.\textsuperscript{3–6} However, recent work suggests that classical theories are unable to predict the formation of structures on certain hetero-epitaxial systems. By comparing numerical results to experimental data, Stepanyuk et al.\textsuperscript{7} showed how quantum mechanical interactions could lead to the self-assembly of one dimensional Co chains and Fe superlattices on Cu(111).\textsuperscript{7,8} More recently, Refs. 9 and 10 used density functional theory (DFT) and kinetic Monte Carlo simulations to show that anisotropy in the quantum mechanical interactions between adsorbed atoms (adatoms) is crucial for the formation of striped dislocation patterns seen when Ag is deposited on Pt(111).\textsuperscript{11}

Motivated by these works, our primary goal in this paper is to derive an analytic expression for the anisotropic surface state\textsuperscript{12,13} (SS) mediated Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction\textsuperscript{14–17} between adatoms on a FCC surface. While perturbative calculations of the RKKY interaction have been performed in 2D by Lau and Kohn\textsuperscript{18} and others,\textsuperscript{19} we emphasize that, to the best of our knowledge, these previous studies only considered isotropic band structures.\textsuperscript{20–22} Our analysis, however, specifically accounts for the anisotropy in the interaction, which is induced by a more realistic SS band. In this paper, we focus our analysis primarily on the the (111) surface of an FCC crystal so that, as a secondary goal, we may compare our results with Refs. 7–10. However, the techniques we employ are easily generalized to other lattice geometries and systems; we will show, for example, how our main result can be used to describe the RKKY interaction on surfaces such as Be(10\bar{1}0) and Cu(110), which both have a highly anisotropic surface state band.\textsuperscript{23}

In Ref. 24, one of us proposed that the main contribution to the RKKY interaction comes from electrons whose Fermi velocity (rather than Fermi wave vector) is parallel to the vector separating the adatoms. A version of this idea was in fact shown earlier by Roth et al.,\textsuperscript{25,26} whose analysis we extend to surfaces and 2D systems. Our main analytical tool will be a stationary phase approximation of the relevant, oscillatory integrals. This technique has the benefit of revealing the essential physics of the RKKY interaction, at the cost of limiting our result to the far-field regime; we provide a criterion that indicates when our result is valid. The generality of our approach is closely related to the stationary phase approximation and stems from the fact that, in the far-field limit, the interaction is determined by the local structure of the Fermi edge (i.e. a few electron states); thus, one need not perform complicated integrals over all surface states.

We find that the 2D RKKY interaction is oscillatory and bounded by an envelope that decays as inverse distance squared, in agreement with experimental and numerical studies.\textsuperscript{7,8,18–21} For a (111) FCC surface, our analysis predicts a six-fold anisotropy in the interaction; however, we find less variation in the interaction wavelength than in Ref. 9. Below we indicate conceptual differences between our approach and those of the afore-
The remainder of the paper is organized as follows. In Section II, we evaluate an analytical formula for the anisotropic, RKKY interaction in 2D. In Section III A we discuss the essential physics of the interaction and give a criterion that indicates when our main result is valid. In Section III B we briefly review experimental evidence of the 2D RKKY interaction, while in Section III C we discuss our main result in the context of Ag on Pt(111) (Refs. 9 and 10). In Section III D 1 we highlight the key quantities needed to determine the RKKY interaction for different lattice geometries, and in Section III D 2 we consider complications that arise in metals such as Be(1010), i.e. when the SS band is centered at special points on the boundary of the surface Brillouin zone. Section III E compares our work with other analytical treatments of the RKKY interaction, and Section III F discusses complications beyond the scope of our work. Section III G explores open questions and extensions of our analysis. Section IV restates our main conclusions.

II. 2D ANISOTROPIC RKKY INTERACTION

It is well known that the {111} surfaces of each noble metal possesses a partially-filled, “metallic” $sp$ Shockley surface state (with its minimum at the zone center $\Gamma$), which can mediate interactions between adatoms. The general form of the corresponding 2D RKKY interaction is
\[
\Delta = -\mathcal{P} \int d^2k d^2k' \frac{e^{-i(k-k')\cdot R}}{E_{k'} - E_k} \{J_{kk'} \}^2 f(E_k)[1-f(E_{k'})],
\]
where $\mathcal{P}$ indicates that the integral should be interpreted as a principal value. The vector $R$ connects the positions of the interacting adatoms. The Fermi function is denoted by $f(E_k)$, and $E_k$ is the energy of a SS with the wave vector $k$. When multiplied by $f(E_k)[1-f(E_{k'})]$, the exchange integral $J_{kk'}$ describes a coupling event whereby a SS below the Fermi energy is upscattered to a state above the Fermi energy via an interaction with an adatom; the conjugate transpose $J_{kk'}^\dagger$ describes the opposite process in which the upscattered SS returns to its original state. The presence of $\exp(-i(k-k')\cdot R)$ reveals that the interaction is mediated by a weighted sum of symmetric and anti-symmetric surface states. Here we refer specifically to the symmetry of $\cos((k-k')\cdot R)$ under the reflections about the midpoint of $R$ (cf. Eq. (4) for motivation). Integration runs over all $k$ in the first Brillouin zone of a single band; we neglect contributions from other bands.

We assume that the coupling between a SS and an adatom is the same at both adatom locations; consequently, $R$ is a Bravais lattice vector. This is a reasonable assumption, since the adatoms typically adsorb at energetically-favored high-symmetry sites (topo, bridge, or center/hollow, depending on the adatom and substrate). In such cases, adatom pairs will be separated by 2D Bravais lattice vectors, regardless of their registry with the substrate. The 2D SS wave vectors $k$ and $k'$, which mediate the interaction, can be regarded as free-electron-like states for the case of the metallic Shockley state, but in general must be treated as Bloch states (cf. Section III D 2).

For simplicity, we assume that one $s$-orbital from each substrate atom contributes to the SS conduction band; we calculate the conduction band using a nearest-neighbor, tight binding approximation, which provides a semi-quantitative approximation for the metallic surface state on Cu(111). For the (111) face of an FCC crystal,
\[
E(k) = \epsilon \left[3 - \cos \left(\frac{2\sqrt{3}}{k} \cdot a_{\parallel} \right)\right] - \cos(k_+ + \cos(k_-)
\]
where $k = (k_x, k_y)/a$; $k_{\pm} = (k \cdot a_{\perp}) \pm (1/\sqrt{3})(k \cdot a_{\parallel})$; \[a_{\parallel} = a(\sin(\theta), \cos(\theta)) \] and $a_{\perp} = a(\cos(\theta), -\sin(\theta))$. The constant $a$ is the inter-atomic spacing of the substrate atoms ($k_x$ and $k_y$ are dimensionless), and $\epsilon$ is a parameter having units of energy. When the crystal axes are held fixed, $-\theta$ is the angular coordinate of $R$. Concerning the rotation angle, however, we adopt the alternate perspective that $R$ is always fixed in the $\hat{y}$ direction, so that the crystal axes are rotated by $\theta$ (cf. Fig. 1): $R = R_\theta \hat{y}$. We make this choice to clarify the analysis; specifically, we anticipate that the dominant contribution to the interaction comes from electrons whose Fermi velocity is parallel to $R$. By applying a stationary phase approximation to Eq. (1), we will show that this idea arises naturally in the rotated frame.

By inversion symmetry, we may replace $1 - f(E_{k'})$ by 1, as this does not change the principal value expression by Eq. (1). We may also simplify Eq. (1) by applying the substitution $k \to k'$ to all $k \to k'$ for which $k_y (k'_y) < 0$. Changing variables from $k_y (k'_y)$ to $E (E')$ then yields,
\[
\Delta = \mathcal{P} \int_0^{E_{\text{max}}} dE \int_0^{E_{\text{max}}} dE' \int dk_x \int dk'_x \frac{f(E) J_{kk'}^2}{E - E'} \times V_{y}^{-1}(E, k_x) V_{y}^{-1}(E', k'_x) P(k_y, k'_y),
\]
where $CC$ stands for “complex conjugate,” and $V_{y}^{-1}(E, k_x) = \partial k_y / \partial E$. The product $\partial V_{y}(E)/\partial E$ is the $k_y$ component of the group velocity of a wave packet centered about $\hbar k$. Note that $k_y = k_y(k_x, E)$. In the limit of large $R$ (we specify this condition more precisely below), the integrand in Eq. (3) oscillates rapidly when $k_y(k_x, E)$ changes as a function of only $k_x$, keeping $E$ fixed. We expect cancellation of the integrand due to destructive interference, except when $\partial k_y / \partial k_x|_E = 0$, when $k_y$ is a maximum on each constant energy curve (cf. Fig. 1). These extrema correspond to a SS whose group velocity is parallel to $R$. 

Concerning the rotations, we note that $R_\theta = R_\theta^{\dagger}$, and $V_{y}(E, k_x) V_{y}(E', k'_x) = V_{y}(E', k'_x) V_{y}(E, k_x)$, so that $V_{y}(E, k_x) V_{y}(E', k'_x) = V_{y}(E', k'_x) V_{y}(E, k_x)$.

The remainder of the paper is organized as follows. In Section II, we evaluate an analytical formula for the anisotropic, RKKY interaction in 2D. In Section III A we discuss the essential physics of the interaction and give a criterion that indicates when our main result is valid. In Section III B we briefly review experimental evidence of the 2D RKKY interaction, while in Section III C we discuss our main result in the context of Ag on Pt(111) (Refs. 9 and 10). In Section III D 1 we highlight the key quantities needed to determine the RKKY interaction for different lattice geometries, and in Section III D 2 we consider complications that arise in metals such as Be(1010), i.e. when the SS band is centered at special points on the boundary of the surface Brillouin zone. Section III E compares our work with other analytical treatments of the RKKY interaction, and Section III F discusses complications beyond the scope of our work. Section III G explores open questions and extensions of our analysis. Section IV restates our main conclusions.
Thus, fix $E$ and expand $k_y$ about its maximum; namely,
\[
k_y(E, k_x) \approx k_y(E, \hat{k}_{x,E}) - (k_x - \hat{k}_{x,E})^2/n(E),
\]
\[
1/n(E) = \frac{1}{2} \frac{\partial^2 k_y(E, k_x)}{\partial k_x^2} \bigg|_{k_y=k_x=k_{x,E}},
\]
where $\hat{k}_{x,E}$ maximizes $k_y(E, k_x)$ for a given $E$. Equation (5) states that for each $E$, there is a group of $k$-states centered around $(\hat{k}_x, k_y(E, \hat{k}_x))$ mediating the interaction in a coherent manner. The function $n(E)$ measures the approximate number of $k$-states that contribute to the interaction for a given $E$. We will show later how Eqs. (3), (5), and (6) provide a more precise definition of the far-field limit.

We substitute Eq. (5) into Eq. (3) and extend the integration in $k_x, k'_x$ from $-\infty$ to $\infty$. Approximating $J_{kk'} \approx J_{kk'}|_{k_y=k_{y,E}, k'_y=k_{y,E}} = J_{EE'}$ and $V_y(E, k_x) \approx V_y(E, \hat{k}_{x,E})$ yields
\[
\Delta = \frac{1}{R} \int_0^{E_{\text{max}}} dE \int_0^{E_{\text{max}}} dE' \left[ f(E) - f(E') \right]^2 \frac{n(E)n(E')}{2|E-E'|V_y(E, k_{x,E})V_y(E', k_{x,E})} \times \left\{ \exp[i(k_y - \hat{k}_{y,E}) R] + i \exp[i(k_y + \hat{k}_{y,E}) R] + CC \right\}.
\]
The substitution $f(E) \rightarrow [f(E) - f(E')]/2$ is valid by inversion symmetry, that is, switching $E$ and $E'$ in Eq. (3) is equivalent to multiplying the expression by $-1$. This substitution eliminates the pole along the real $E$ axis, so that Eq. (7) is the principal value of Eq. (3).

In the spirit of Ref. 25, we assume that the major contribution to Eq. (7) comes from the Fermi energy, $\epsilon_F$. We make the substitution $E = E' = \epsilon_F$ and approximate $k_y|_{k_y=\epsilon_F} \approx \hat{k}_{y,F} + V_y^{-1}(E - \epsilon_F)$, neglecting terms $O(E - \epsilon_F)^2$.

The vector $\mathbf{K}_F = (\hat{k}_{x,F}, \hat{k}_{y,F})$ points to maximum of the Fermi edge in the rotated reference frame, and $V_F = V_y(\epsilon_F, \hat{k}_{y,F})$ is proportional to the Fermi velocity $v_F$ via $V_F = h v_F/a$. Hereafter, for brevity, we refer to $\hat{k}_{y,F}$ as $k_y$; the subscript $s$ is intended to remind the reader that $2 k_F$ spans the Fermi edge.

When the limits of integration are extended to $\pm \infty$, Eq. (7) simplifies to
\[
\Delta = \frac{\pi |J_{x,F,EF}|^2 n(\epsilon_F)}{2 V_F^2 R} \int_0^\infty dE \int_0^\infty dE' \frac{f(E) - f(E')}{E - E'} \times \left\{ e^{i \epsilon_F (E - E')} R - i e^{i (2k_F + V_F^{-1}(E + E' - 2\epsilon_F)) R} + CC \right\}.
\]
Equation (8) can be evaluated by the residue theorem. By definition, $f(E) = \{\exp[E - \mu]/\tau + 1\}^{-1} \approx \{\exp[E - \epsilon_F]/\tau + 1\}^{-1}$ (the Fermi velocity, and $\tau = k_F T$ is Boltzmann’s constant times the temperature); the Fermi function has poles at $E = \epsilon_F \pm (2n+1)\pi i \tau$, $n = 0, 1, 2, \ldots$. Carrying out the two integrations yields an odd-power geometric series, which reduces to
\[
\Delta = -2\pi^3 \tau \frac{|J_{x,F,EF}|^2 n(\epsilon_F)}{V_F^2} \sin(2k_F R) \frac{\sin(2k_F R)}{2\pi \tau R / V_F} R.
\]
We emphasize that the wavelength of this oscillatory expression is $\pi/k_s$, where $k_s = k_{y,F}$ is the projection onto the unit vector $\mathbf{R}$ of the Fermi wavevector whose velocity is parallel to $\mathbf{R}$; i.e., it is $\pi R / (k_F \cdot \mathbf{R})$. We treat $J_{x,F,EF}$ as a free parameter; strictly speaking then, Eq. 9 is well defined only for $\mathbf{R}$ a Bravais lattice vector. This becomes important when the surface state does not have simple 2D free-electron behavior (cf. Section III D 2). The factor of $\tau$ appearing in the coefficient of (9) comes from the ratio $E/\tau$ in the chemical potential.

To complete the analysis, we must compute $V_y(E, k_x)$, $k_x$, and $n(E)$. Implicit differentiation of Eq. (2) with respect to $k_y$, keeping $k_x$ fixed, gives $V_y(E, k_x)$:
\[
V_y(E, k_x) = \frac{\partial E}{\partial k_y|_{k_x}} = \alpha \epsilon \left[ \frac{2}{\sqrt{3}} \cos(\theta) \sin(k_a) - (\mathbf{p} \cdot \mathbf{a})(\sin(k_-) - (\mathbf{q} \cdot \mathbf{a})(\sin(k_+)),
\]
where $\mathbf{p} = a^{-1}(1, 1, 1/\sqrt{3})$, $\mathbf{q} = a^{-1}(1, -1, 1/\sqrt{3})$. To find $\hat{k}_{y,F}$, differentiate Eq. (2) with respect to $k_x$ for fixed
$E$, which gives
\[ 0 = \frac{\partial k_y}{\partial k_x} = (2\sqrt{3})\sin(\theta) \sin(k_{||}) + (\mathbf{p} \cdot \mathbf{a}_\perp) \sin(k_-) \\
+ (\mathbf{q} \cdot \mathbf{a}_\perp) \sin(k_+). \tag{11} \]

Solving Eqns. (2) and (11) simultaneously yields $k_y(E)$ and $k_x(E)$. Equation (6) defines $n(E)$; using Eq. (11) and $\partial k_y/\partial k_x|_{k_x=k_y}=0$ one finds,
\[ n(E)^{-1} = \frac{1}{2} ((4/3) \sin^2(\theta) \cos(k_{||}) + (\mathbf{p} \cdot \mathbf{a}_\perp)^2 \cos(k_-) \\
+ (\mathbf{p} \cdot \mathbf{a}_\perp)^2 \cos(\bar{k}_+) / ((2/3) \sin(k_{||} - (\mathbf{p} \cdot \mathbf{a}_\perp) \sin(\bar{k}_-) - (\mathbf{q} \cdot \mathbf{a}_\perp) \sin(\bar{k}_+)), \tag{12} \]
where $\bar{k} = (k_x, k_y)$ and $\bar{k}_\perp = k_{\perp}(k_x, k_y)$.

### III. DISCUSSION

#### A. Elements of the 2D RKKY interaction for a (111) FCC surface

Equations (2) and (9)-(12) completely describe the RKKY interaction for a (111) FCC surface. The essential physics, however, is manifest in Eq. (9). Specifically: (i) the interaction becomes stronger as more SS contribute ($n(\epsilon_F)$ increases) and/or the coupling between a SS and an adatom becomes stronger ($|J_{\epsilon_F}|^2$ increases); (ii) the interaction amplitude decreases as the SS Fermi velocity increases ($V_F$ increases); and (iii) the interaction oscillates with a periodicity determined by $2k_s$, twice the $k_y$ component of the SS Fermi wave vector corresponding to the Fermi velocity that is parallel to $\mathbf{R}$. The oscillations arise from the symmetry (with respect to $\mathbf{R}$) of the SS mediating the interaction.

When $\tau \to 0$, Eq. (9) decays as $1/R^2$. The low temperature limit is defined by estimating $V_F = \mathcal{O}(\hbar^2 k_F/a m_\text{eff})$, where $k_F$ and $m_\text{eff}$ are the Fermi wave vector and effective mass of the SS. For Ag (111), Table 1 of Ref. 20 gives experimental values of these quantities; one finds that $1 \text{ eV} \lesssim V_F \lesssim 10 \text{ eV}$, so that Eq. (9) decays as $1/R^2$ whenever $R\tau \ll 1$. At room temperature ($\tau = 1/40 \text{ eV}$), for example, we estimate that such an exponential decay in Eq. (9) only becomes appreciable when $R a > 10a$ for this system (recall that $a$ is the inter-atomic distance).

Equation (9) differs in several respects from its 3D counterpart. In the bulk of a crystal, the RKKY interaction falls off as $1/R^3$ when $\tau = 0$, due to the increased dimensionality of the lattice.\textsuperscript{25} Also, in 3D the number of electrons contributing to the interaction is proportional to $n(\epsilon_F)^2$, since the dominant electrons live on a Fermi surface (as opposed to an edge).

Numerically solving the system of Eqqs. (2) and (11) for $\bar{k}$ reveals that $k_y$ is a function of $\theta$ (cf. Figs. 1 and 2). This implies that anisotropy in the SS band structure induces anisotropy in both the amplitude (via $V_F$ and $n(\epsilon_F)$) and the periodicity of the interaction (cf. Fig. 2). From the structure of the lattice, we find (i) that the anisotropy is six-fold, and (ii) that the interaction amplitude is strongest for $\theta = 0, \pi/3, 2\pi/3, \ldots$, i.e. when $\mathbf{R}$ is perpendicular to the flattest part of the Fermi edge (cf. Figs. 1 - 3).

Inspection of Fig. 1, however, reveals that the SS band structure is nearly isotropic when $E/\epsilon \lesssim 3$. This observation is confirmed by expanding Eq. (2) for small $\mathbf{k}$;
\[ \frac{E(|\mathbf{k}|)}{\epsilon} \approx (a|\mathbf{k}|)^2 - \frac{(a|\mathbf{k}|)^4}{12} + \frac{(10 + \cos(6\theta))(a|\mathbf{k}|)^6}{3240}. \tag{13} \]

The dispersion relation is isotropic up through $\mathcal{O}(|\mathbf{k}|^4)$. When the Fermi energy $\epsilon_F/\epsilon \lesssim 3$, the component $k_s, k' = 0$ and $a_k \approx 6^{1/2}[1 + \sqrt{1/(\epsilon_F/3\epsilon)}]^{1/2}$. In this limit, the interaction given by Eq. (9) is approximately independent of $\theta$ (cf. Fig. 2). Anisotropy in the interaction becomes apparent only when $\epsilon_F/\epsilon \gtrsim 3$.

We identify the far-field regime by determining the minimum values of $R$ for which our model is valid. Returning to Eqqs. (3) and (7), when $R/n(\epsilon_F) \ll 1$, extending the limits of integration of $k_x, k'_x$ to infinity grossly overestimates the number of $k$-states contributing to the interaction. In particular, for $E/\epsilon_F = 4$ and $\theta = 0$, the amplitude of the interaction diverges, which indicates a total failure of the approximation for all $R$ at this angle. Hence, Eq. (9) is valid, provided that not too many $k$-states contribute to the interaction; namely, $R/n(\epsilon_F) \approx 1$ (cf. Fig. 3). When the opposite limit holds ($R/n(\epsilon_F) \ll 1$), Eq. (9) can be corrected by not extending the limits of integration of $k_x, k'_x$ to $\pm \infty$ in Eq. (3); e.g. for $\theta = 0$ and $\epsilon_F/\epsilon = 4$, a suitable range of integration in $k_x, k'_x$ would be $[-\pi/2, \pi/2]$, which corresponds to the length of a side of the $E/\epsilon = 4$ constant energy

FIG. 2. RKKY interaction $-\Delta/\langle |J_{\epsilon_F,\epsilon_F}|^2 \rangle$ (Eq. (9)) on a (111) FCC surface as a function of $\theta$ at zero temperature when $\epsilon_F/\epsilon = 3$. Values of $\theta$ are approximately the angles an adatom makes with its second, fourth, sixth, eighth, and first nearest neighbors, from bottom to top. All curves oscillate about zero, indicated for each curve by a dashed line; these lines are separated by intervals of 1/2 along the vertical axis.
The function $n(\epsilon_f/\epsilon)$ of the constant energy contour maxima for different angles (cf. Eqs. (5) and (12)). Note that for $\theta = 0$ the amplitude diverges when $\epsilon_f/\epsilon \rightarrow 4$, so that Eq. (5) overestimates the number of surface states contributing to the interaction. For all other values of $\theta$, $n(\epsilon_f/\epsilon) \rightarrow 0$ when $\epsilon_f/\epsilon \rightarrow 4$, since the maximum of the constant energy curves becomes infinitely sharp in this limit. The far-field regime in which Eq. (9) is valid is given by $R/n(\epsilon_f/\epsilon) \gg 1$.

**B. Experimental evidence of isotropic 2D RKKY interactions**

At low temperatures, STM measurements of Co adatoms on Cu(111) are capable of directly imaging standing waves in the electronic density of states (DOS).\(^{37}\) By comparing such experiments with DFT calculations (based on the Korringa-Kohn-Rostoker (KKR) Green’s function method) of the SS mediated interaction, Stepanyuk et al.\(^{7}\) showed that the envelope bounding oscillations in the interaction energy falls off as $1/R^2$ for distances larger than roughly ten atomic spacings.\(^{36}\) In the far-field limit, this implied that i) the interaction is dominated by the SS, and ii) bulk electronic states do not contribute to the $\mathbf{R}$-dependence of the coupling between adatoms. Stepanyuk et al. also found that the interaction wavelength is $\pi/k_F$ at large distances. At short and intermediate distances (corresponding to $R \lesssim 10$ in our model), they found that screening by bulk electrons affects the location of the first energy minimum.

These conclusions are in agreement with our main result, Eq. (9). In particular, we note that the Fermi energy for Cu(111) is well within the quadratic regime;\(^{30}\) Eq. (9) thus predicts that the interaction is isotropic, as seen in Fig. 2 of Ref. 7. We estimate also that the corresponding ratio $\epsilon_f/\epsilon \lesssim 1$, which suggests $n(\epsilon_f/\epsilon) \lesssim 1$ (cf. Fig. 3). The far-field limit, defined as $R/n(\epsilon_f/\epsilon) \gg 1$, should be satisfied for Cu(111) at distances $R \gtrsim 10$ (at least ten atomic spacings), in agreement with the results of Ref. 7; corrections to Eq. (9) are $O(R^{-1}) - \lesssim 10\%$ as large as the leading-order expression for the interaction.

**C. The anisotropic interaction on Ag(111)**

In Ref. 10, the SS-mediated adatom interaction is calculated in the far-field regime for an Ag(111) surface using DFT. Our analysis agrees with their results, insofar as Eq. (9) predicts a six-fold anisotropy in the interaction wavelength. However, Ref. 10 predicts that the wavelength may change by almost 50% as a function of $\theta$. Comparing their numerics with our (one parameter) band structure suggests that $\epsilon_f/\epsilon < 0.5$ for strained Ag(111), so that Eq. (13) is a good approximation to Eq. (2), and Eq. (9) is well within the isotropic regime. Since the tight-binding ansatz might modestly underestimate the actual leading-order anisotropy, we considered the effect of enhancing this anisotropy by an order of magnitude; to more emphatically rule out the role of the leading-order anisotropy, we also examined the effect of enhancement by 2 and by 3 orders of magnitude. Our conclusion remains valid even when the anisotropy in Eq. (13) is increased by $10^3$ (cf. Fig. 4). Thus, our analysis predicts negligible anisotropy in the adatom interaction on Ag.

Reference 10 also indicates that the amplitude of the interaction can decrease by as little as a factor of two over five or six atomic lengths; this does not agree with the $1/R^2$ envelope bounding oscillations in Eq. (9). Our analysis therefore implies that the SS-mediated RKKY interaction alone cannot account for the results found in Refs. 9 and 10.

Our model does not incorporate surface stress.\(^{37}\) In Ag/Pt systems, lattice mismatch creates strain in the Ag layers, which in principle affects the band structure of the SS. References 9 and 10 included the effects of strain in their DFT calculations, which could account for discrepancies between Eq. (9) and their results. Furthermore, Eq. (1) neglects certain quantum mechanical effects\(^{17}\) (e.g. correlation energies) which are in principle incorporated into DFT; such effects could be responsible for the variation of the interaction found in Refs. 9 and 10.

**D. Extensions to other systems**

1. Key quantities determining the RKKY interaction

The steps leading to Eq. (9) can easily be generalized to systems having different band structures or indirect coupling modes. Our key approximation is that, in the far-field limit, Eq. (1) is dominated by the local behavior of the band structure at the points where the Fermi velocity is parallel or anti-parallel to the adatom separation vector. This local behavior is contained explicitly in Eq. (6), and the implementation of our approximation.
FIG. 4. Equations (2) and (13) as functions of $k$ for $\theta = 0$ and $\theta = 30^\circ$. For Eq. (13), we also magnify the leading order anisotropy, $[1 + \cos(6\theta)](a|k|)^6/3240$, by factors of 10, 100, and 1000. For $\epsilon_F/\epsilon < 0.5$ (corresponding to Ag(111)), the inset shows that even with a thousandfold enhancement, the leading order anisotropy does not contribute significantly to the band structure in the vicinity of the Fermi energy. Consequently, our model predicts an isotropic RKKY interaction between adatoms on Ag(111).

2. Surface states at special points on the SBZ edges

On the (110) faces of Cu, Ag, and Au, there is a metallic surface state centered at $\bar{Y}$, the middle of the longer edge of the rectangular surface Brillouin zone. There is no reason to expect that these SSs are isotropic; indeed, Simon et al. calculate the semi-minor and semi-major axes of the elliptical Fermi edge on Cu to be 1.38 nm$^{-1}$ and 1.64 nm$^{-1}$, respectively, with a ratio 0.84. In their computation of RKKY interactions in these principal directions, they find what amounts to $\pi/\lambda_F = 1.41$ nm$^{-1}$ and 1.72 nm$^{-1}$, respectively.

For the unusual hcp metal beryllium, there are similar observations. On the close-packed, basal, (0001) face there is a nearly isotropic metallic surface state centered at $\bar{T}$. On Be(1010) there is a metallic surface state with its minimum at $\bar{A}$, the center of the longer edge of the rectangular surface Brillouin zone, with anisotropic (elliptical) constant-energy contours and consequent anisotropy in the resulting RKKY interactions. The Fermi ellipse is more eccentric than that of Cu(110), with an aspect ratio about 0.71 (and semiaxes 2.2 nm$^{-1}$ and 3.1 nm$^{-1}$). The ratio of the wavelengths of charge-density oscillations spawned by step edges in the two principal directions have a similar, though slightly higher, ratio around 0.74. However, we are not aware of any data for the dependence of oscillations on steps with arbitrary azimuthal orientation that would allow comparison with our analysis. Charge-density oscillations were also observed around pointlike scatterers. The experiments noted the asymmetry of these contours.
Assuming an elliptical Fermi edge, we can apply Eq. (9b) to predict the azimuthal dependence of the RKKY interaction for Be(1010) as well as Cu(110). In Fig. 5 we carry out this task for Be(1010) by numerically computing n(ε_F) and k_F. The plot shows interaction energy as a function of azimuthal orientation and distance from a central atom. The inset shows the upper half of the rectangular first surface Brillouin zone. Recalling the discussion after Eq. (1), we re-emphasize that when comparing energies given by Eq. (9) and Fig. 5, care must be taken to ensure that ⃗R is a Bravais lattice vector.

We note that as a consequence, the vector ⃗k_F underlying k_s in Eq. (9) is only determined modulo the addition of a reciprocal lattice vector. The crucial quantity in Eq. (9) is \( \text{sgn}[V_F] 2 k_s \cdot ⃗R = \text{sgn}[V_F] 2 k_F \cdot ⃗R \), where sgn is the sign function. The above product is invariant (modulo factors of 2π) under subtraction of a reciprocal lattice vector \( \vec{G} \) from any change of sign in \( \vec{k}_F \cdot \vec{R} \) will be accompanied by a corresponding change of sign in \( V_F \) (see Fig. 5, for example). The two wavevectors \( \vec{k}_F \) and \( \vec{k}_F - \frac{1}{2} \vec{G} \) then correspond to different choices of the origin in \( \vec{k} \)-space.

In Fig. 5 we show two possible choices \( \vec{k}_F \) having \( \Gamma \) and \( A \) as their respective origins. When applying Eq. (9) to Be(1010) we can view the Fermi contour as a single contiguous ellipse with “inner” spanning vectors across it and energy gradients pointing outward, rather than (or as well as) a pair of semiellipses with “outer” spanning vectors across the SBZ and with inward pointing (toward \( \Gamma \)) gradients. We note that when used in conjunction with Eq. (9), different choices of \( \vec{k}_F \) will result in different (and physically unmeaningful) interpolations of the interaction between Bravais lattice points.

**E. Comparison to other analytical approaches**

In Ref. 20 Hyldgaard and Persson calculate the SS-mediated adatom interaction using a technique based on the Harris energy functional.\(^{45,46}\) Their approach yields a non-perturbative, analytic estimate of the indirect interaction that accounts for i) a phase shift, which occurs when a SS scatters from an adatom, and ii) damping of the interaction amplitude due to screening by bulk atoms.

While both of these effects are seen in some experimental systems,\(^ {49}\) we emphasize that they arise from localized aspects of adatom coupling to the SS and so do not affect the characteristic wavelength or decay of the interaction. Since our main task is to account for anisotropy in the adatom-pair interaction, we choose not to complicate our calculation with these effects to avoid clouding our discussion on the origin of anisotropy. Analytically, this choice was made when we set the exchange integral |\( J_{kk} \)| equal to a constant; as this term describes the detailed coupling between an adatom and surface state, its careful evaluation should yield information about the phase shift and screening.

**F. Systems with complications not considered in the present analysis**

For heavy metals, spin-orbit coupling plays a significant role in determining the SS band structure; for the present problem, it leads to splittings of SS bands, called Bychkov-Rashba splitting.\(^ {46,47}\) Perhaps the most widely known example is the metallic surface state on Au (111) at \( \Gamma \), in the L-gap of the projected band states, for which a splitting of 0.25 nm\(^{-1} \) — with no detectable azimuthal dependence — is observed (viz., \( k_F = 1.72, 1.97 \) nm\(^{-1} \)).\(^ {48,49}\) Excellent agreement is obtained with fully relativistic DFT calculations,\(^ {49}\) while a simple tight-binding model\(^ {50}\) yields a splitting several orders of magnitude smaller than the relativistic calculations.\(^ {49}\) In fits of their calculations of the RKKY exchange interaction, Simon et al.\(^ {40}\) obtained good agreement with their calculated results by using the sum of two oscillatory curves with \( k_F = 1.04, 1.42 \) nm\(^{-1} \).\(^ {51}\)

The distinctive semi-metal Bi displays the strongest reported spin-orbit splitting of surface bands, thrice that in Au, and considerable anisotropy.\(^ {53}\) Furthermore, theoretical analysis for Bi is more taxing: For Au(111) one can adequately describe the electronic dispersion by adding a Rashba term to the nonrelativistic Hamiltonian, since the SS is free-electron-like and centered at \( \Gamma \); consequently, the splitting is linear in \( k \).\(^ {53}\) For Bi, the surface states are not free-electron-like and are distributed over the surface Brillouin zone; hence, first-principles relativistic band structure methods are needed to model the complex behavior SS dispersion.\(^ {53}\) For the (111) surface there are six elongated hole pockets along \( \Gamma M \) surrounding a ring-shaped electron pocket centered at \( \Gamma \), all with 2D character.\(^ {53,54}\) Spin-orbit coupling not only decreases the size of the Fermi surface hexagon by 30% but also introduces hole lobes and turns the SS into a surface resonance. On the (110) surface there is a hole metallic surface band centered at \( \Gamma \), and only one branch of the split state can be observed.\(^ {53,55}\) On the (001) surface, there is a hexagonal electron pocket around \( \Gamma \) and six hole lobes along the \( \Gamma - M \) directions, as well as indication of an electron pocket around \( M \).\(^ {52,53,56}\)

When considering exchange coupling between magnetic adatoms, spin orbit coupling introduces another complication: the exchange coupling can lead to canting of the two spins in a coupled pair,\(^ {57}\) which often must be neglected to make calculations feasible.\(^ {58}\)

Another complication is that surface states can produce surface relaxation.\(^ {59}\) In particular, unusually large inward relaxations were noted on Cu(110)\(^ {60}\) and Be(1010).\(^ {61}\) Lateral relaxations due to perturbations are known to complicate the description of lattice gases in terms of adsorbate interactions.\(^ {62}\)

In graphene all one-electron states are ipso facto 2D states. Not surprisingly, then, many theory groups have recently devoted attention to the prospect of RKKY interactions.\(^ {63-74}\) They and others pointed out a variety of complicating issues and idiosyncrasies of mono-
layer graphene, such as the bipartite nature of the lattice (leading to ferromagnetic or repulsive coupling for
impurities on the same hexagonal, Bravais sublattice of the honeycomb graphene lattice\(^63,64\) and antiferromag-
netic or attractive coupling when on opposite Bravais sublattices,\(^64,65,68,69\)), the vanishing density of states at
the Fermi level in undoped and ungated lattices, the suppression of backscattering (leading to \(R^{-3}\) rather than
\(R^{-2}\) decay\(^75\)),\(^63,64\) the role of electron-electron interactions,\(^79\) etc. Usually the adsorbates are taken in
atop sites but sometimes in bridge sites above bonds or hollow sites at the center of the hexagon.\(^63,71\) Since the
Dirac cones are circularly symmetric, our analysis sug-
gests that there should not be anisotropy in the RKKY
interaction, but this neglects the chiral nature of the elec-
trons: sizable three-fold anisotropy is observed, which is
typically attributed to intervalley scattering.\(^67,71\) Hence,
more detailed discussion of graphene is inappropriate
here and distracting from the theme of this paper. Fur-
thermore, actually observing the asymptotic oscillatory
behavior typifying RKKY will generally pose a great
challenge unless the graphene is heavily doped.

In topological insulators, a combination of spin-orbit
coupling and time-reversal symmetry leads to protected
metallic surface states.\(^76\) Thus, RKKY interactions can
be expected to play an important role. Examples of very
recent studies are Refs. 77, 78, and 79.

G. Open Directions

Our analysis could in principle be extended to treat
trio (three-adatom non-pairwise) interactions.\(^24,80\) Such
interactions typically decay asymptotically as \(d^{5/2}\),
where \(d\) is the perimeter of the triangle made by the three
interacting adatoms.\(^81\) While any particular trio interac-
tion is expected to be weaker than the three associated
pair interactions, the difference in the decay envelope is
just a half power (5/2 vs. 2) for SS mediation. More
significantly, the multiplicity of trios is greater; hence,
trio interactions could still play a prominent role in
the ordering of surface structures. The resulting extension
of Eq. (9) would in general contain three different wave-
lengths and would be cumbersome to apply. This analysis
is beyond the scope of the present study. We also note
that multi-site non-pairwise interactions between four or
more adatoms could come into play, with even greater
multiplicities and modest increases in the decay envelope.
Checking how such a series converges to the energy of
an ordered fractional overlayer was challenge never fully
met for rapidly decaying (\(\propto R^{-5}\)) interactions mediated
by bulk states.\(^82\) For an overlayer determined by surface-
state mediated interactions, with density so sparse that
asymptotic interactions determine the ground state, ver-
ifying convergence would present a truly daunting task!

IV. CONCLUSION

In this paper, we derive an analytic formula for the sur-
face state mediated RKKY interaction between adatoms.
The main contribution to the interaction comes from sur-
face states whose Fermi velocity is parallel to the vec-
tor connecting the adatoms. The interaction is oscil-
latory and has an envelope that falls off as \(1/R^2\) (but
eventually transitioning, at finite temperature, to expo-
nential decay at distances larger than germane to this
problem), in agreement with experimental results for
Cu(111).\(^7,8\) The amplitude and frequency of the inter-
action are anisotropic; they depend on the surface state
dispersion relation. Comparison with Refs. 9 and 10 in-
dicate that the RKKY interaction alone, at least to the
extent that the SS dispersion is adequately described by
the tight-binding model, cannot be responsible for the
anisotropy in the interaction between Ag adatoms adsorbed
on Pt (111). Our work suggests that analytic treatment of other quantum mechanical interactions (e.g.
 arising from correlations) and/or strain-induced effects in
the SS band structure may be necessary to account for
this anisotropy. We also show how our analysis can be
applied to other systems such as Be(10\,1\,0) and discuss
extensions of our work to multi-adatom interactions.

ACKNOWLEDGEMENTS

This work was supported by the NSF MRSEC un-
der Grant DMR 05-20471 at the University of Maryland,
with ancillary support from CNAM. Support for PP was
also provided by the National Institute of Standards and
Technology American Recovery and Reinvestment Act
Measurement Science and Engineering Fellowship Pro-
gram Award 70NANB10H026 through the University of
Maryland. TLE was secondarily supported by NSF grant
CHE-07-50334. The authors also with to thank Dioni-
sios Margetis, Gregg Gallatin, and Mark Stiles for use-
ful comments and discussion during preparation of this
manuscript. TLE acknowledges fruitful collaboration
with Per Hyldgaard and, more recently, Kristian Berland
on related problems.
In studying the oscillatory exchange coupling of magnetic multilayers, F. Herman and R. Schrieffer [Phys. Rev. B 46, 5806 (1992)] showed that long-period superoscillations in the RKKY coupling could be explained by generalizing plane-wave functions to Bloch functions, as well as incorporating boundary scattering at the film edges. The latter effect is irrelevant here, and we do not complicate our analysis with the former, given that there is no evidence for analogous superoscillations in adatom-adatom interactions.

In this context, the expression $g = \mathcal{O}(\delta)$ signifies that $g/\delta$ is bounded by constant as $\delta \to 0$.

Calculations of a similar nature were performed for Co adsorbates on Pt(111) 58, for which the Shockley state is empty, and for Co and Fe on the principal faces of Cu and Au 40. In the latter, interactions were computed out to at least 20 neighbor spacings, but there is no discussion of anisotropy for the (111) faces.

For justification, see for example: C. M. Bender and S. Orszag, Advanced Mathematical Methods for Scientists and Engineers (Springer, New York, 1999), pp. 276 - 279.

Following Ref. 25, we assume that $J_{kk'}$ is a slowly varying function of $k$ and $k'$.

In this context, the expression $g = \mathcal{O}(\delta)$ signifies that $g/\delta$ is bounded by constant as $\delta \to 0$. Calculations of a similar nature were performed for Co adsorbates on Pt(111) 58, for which the Shockley state is empty, and for Co and Fe on the principal faces of Cu and Au 40. In the latter, interactions were computed out to at least 20 neighbor spacings, but there is no discussion of anisotropy for the (111) faces.

Our model also does not include spin-orbit coupling for Ag(111), since it is not seen experimentally. From theory, a splitting of 0.013 nm$^{-1}$ is expected, an order of magnitude below the experimental angular resolution, as discussed in Ref. [49].

For the (100) surface, considerable analytical progress on constituent Green’s functions can be made before performing asymptotic approximations, G. D. Mahan, Int. J. Mod. Phys. B 9, 1327 (1995). See also T. L. Einstein, Surf. Sci. 75, L161 (1978). We have not been able to generalize this approach to the geometry of the (111) case and so adopt an approach in the tradition of Lau and Kohn; see Ref. 18, for example.

In studying the oscillatory exchange coupling of magnetic multilayers, F. Herman and R. Schrieffer [Phys. Rev. B 46, 5806 (1992)] showed that long-period superoscillations in the RKKY coupling could be explained by generalizing plane-wave functions to Bloch functions, as well as incorporating boundary scattering at the film edges. The latter effect is irrelevant here, and we do not complicate our analysis with the former, given that there is no evidence for analogous superoscillations in adatom-adatom interactions.

Simon et al. attribute their smaller values of $k_F$ to the imprecise treatment of the surface potential in their calculational scheme.
L. Zhou, J. Wiebe, S. Lounis, E. Vedmedenko, F. Meier, S. Blügel, P. H. Dederichs, and R. Wiesendanger, Nat. Phys. 6, 187 (2010). In earlier work members of this group [J. Wiebe, F. Meier, K. Hashimoto, G. Bihlmayer, S. Blügel, P. Ferriani, S. Heinze, and R. Wiesendanger, Phys. Rev. B 72, 193406 (2005)] found that on clean Pt(111) the Shockley state is unoccupied (non-metallic), but that some bulk bands contribute strongly to the local density of states at the surface. Zhou et al. find strong directional dependence in the RKKY interaction and can fit to the generic 2D expression in the close-packed [110] direction.
