Model of quantum depinning of magnetic vortex cores from line defects in a disk geometry and under the application of an in-plane magnetic field has been developed within the framework of the Caldeira-Leggett theory. The corresponding instanton solutions are computed for several values of the magnetic field. Expressions for the crossover temperature T_c and for the depinning rate $\Gamma(T)$ are obtained. Fitting of the theory parameters to experimental data is presented.

I. INTRODUCTION

Quantum tunneling of mesoscopic solid-state objects has been intensively studied in the past. Examples include single domain particles¹⁻³, domain walls in magnets⁴⁻⁶, magnetic clusters^{7,8}, flux lines in type-II superconductors^{9,10} and normal-superconducting interfaces in type-I superconductors^{11,12}. It is well known that micron-size circular disks made of soft ferromagnetic materials exhibit the *vortex state* as the ground state of the system for a wide variety of diameters and thicknesses¹³⁻¹⁶. This essentially non-uniform magnetic configuration is characterized by the curling of the magnetization in the plane of the disk, leaving virtually no magnetic “charges”^{17,18}. The very weak uncompensated magnetic moment of the disk sticks out of a small area confined to the vortex core (VC). The diameter of the core is comparable to the material exchange length and has a weak dependence on the dot thickness^{18,19}. Because of the strong exchange interaction among the out-of-plane spins in the VC, it behaves as an independent entity of mesoscopic size.

Recent experimental works have reported that the dynamics of the VC can be affected by the presence of structural defects in the sample²⁰⁻²³. This is indicative of the elastic nature of the VC line, whose finite elasticity is provided by the exchange interaction²⁴. In Ref. 22 non-thermal magnetic relaxations under the application of an in-plane magnetic field are reported below $T = 9$ K. It is attributed to the macroscopic quantum tunneling of the elastic VC line through pinning barriers when relaxing towards its equilibrium position. In such range of low temperatures only the softest dynamical mode can be activated, which corresponds to the gyrotropic motion of the vortex state. It consists of the spiral-like precessional motion of the VC as a whole²⁵⁻²⁹ and can also be viewed as the uniform precession of the magnetic moment of the disk due to the vortex. The gyrotropic mode is intrinsically distinct from conventional spin wave excitations: in the latter case, it is worth noting that the VC has a significant influence on the form of spin-wave mode eigenfunctions in thin disks^{30,31} and in disks with

moderate aspect ratio³²⁻³⁴.

The aim of this paper is to study the mechanism of quantum tunneling of the elastic VC line through a pinning barrier during the gyrotropic motion. We focus our attention on line defects, which can be originated for instance by linear dislocations along the disk symmetry axis. This case may be relevant to experiments performed in Ref. 22 since linear defects provide the maximum pinning and, therefore, the VC line in the equilibrium state is likely to align locally with these defects. Such a situation would be similar to pinning of domain walls by interfaces and grain boundaries. Thus, we are considering the depinning of a small segment of the VC line from a line defect. The problem of quantum and thermal depinning of a massive elastic string trapped in a linear defect and subject to a small driving force was considered by Skvortsov³⁵. The problem studied here is different as it involves gyrotropic motion of a massless vortex that is equivalent to the motion of a trapped charged string in a magnetic field²⁴. We study this problem with account of Caldeira-Leggett type dissipation.

The paper is structured as follows. In Sec. II the Lagrangian formalism of the generalized Thiele’s equation is presented and Caldeira-Leggett theory is applied to obtain the depinning rate. The imaginary-time dynamical equation for instantons is derived in Section III and numerical solutions are computed. In Section IV the crossover temperature between the quantum and thermal regime is obtained. Discussion and fitting of the theory parameters (which is related to the pinning potential) to experimental data are provided in Sec. V. Final conclusions are included in this section.

II. ELASTIC THIELE’S LAGRANGIAN FORMALISM AND DEPINNING RATE

In this paper we restrict ourselves to a circular disk geometry and to an applied in-plane magnetic field configuration. The VC line is pinned by the line defect going in the Z direction (symmetry axis of the disk) at the center of the disk. The vortex line shall be described by the vector field $\vec{X} = (x, y)$, where $x(t, z)$ and $y(t, z)$ are co-

ordinates of the center of the VC in the XY plane. The dependence on the Z -coordinate emerges from the elastic nature of this magnetic structure. Figure 1 shows an sketch of the vortex line deformation due to pinning and its gyroscopic motion.

FIG. 1: (Color online) Vortex state and depinning via nucleation of the part of the VC line in a circular disk made of soft ferromagnetic material.

The softest dynamical mode of the VC, and hence of the whole vortex, originates from gyroscopic motion and it is described by the generalized Thiele's equation²⁴:

$$\dot{\vec{X}}(t, z) \times \vec{\rho}_G + \partial_z \vec{\Pi}_z + \nabla_{\vec{X}} \omega = 0, \quad (1)$$

where $\dot{}$ means time derivative. The gyrovector density³⁶ $\vec{\rho}_G = \rho_G \hat{e}_z$ is responsible for the gyroscopic motion of the VC and its modulus is given by $\rho_G = 2\pi p n_v M_s / \gamma$, where M_s is the saturation magnetization, γ is the gyromagnetic ratio, $p = \pm 1$ is the polarization of the VC and $n_v = \pm 1$ is the chirality of the magnetization of the disk. The potential energy density $\omega(\vec{X}, \partial_z \vec{X})$ splits into the sum of two contributions, $\omega_1(\vec{X})$ and $\omega_2(\partial_z \vec{X})$. The latter is the elastic energy term, $\omega_2(\partial_z \vec{X}) = \frac{1}{2} \lambda \left(\frac{\partial \vec{X}}{\partial z} \right)^2$, which is provided by the exchange interaction. The elastic constant is given by $\lambda = 2\pi A \ln(R/\Delta_0)$, where R is the radius of the disk, A is the exchange stiffness constant and $\Delta_0 = \sqrt{A/M_s^2}$ is the exchange length of the ferromagnetic material. Finally, $\vec{\Pi}_z = -\delta\omega/\delta(\partial_z \vec{X}) = -\lambda \partial_z \vec{X}$ is the generalized momentum density with respect to Z . Consequently, the generalized Thiele's equation becomes

$$\dot{\vec{X}}(t, z) \times \vec{\rho}_G - \lambda \partial_z^2 \vec{X}(t, z) + \nabla_{\vec{X}} \omega = 0 \quad (2)$$

Let L be the thickness of the circular disk. The Lagrangian corresponding to the above equation is given

by²⁴

$$\mathcal{L}[t, \vec{X}, \dot{\vec{X}}, \partial_z \vec{X}] = \int_0^L dz \left\{ \dot{\vec{X}} \cdot \vec{A}_{\rho_G} - \omega(\vec{X}, \partial_z \vec{X}) \right\}, \quad (3)$$

where $\vec{A}_{\rho_G} = \rho_G y \hat{e}_x$ is the gyrovector potential in a convenient gauge³⁷. The VC is a mesoscopic object consisting of many degrees of freedom. Quantum depinning of such object must be considered within semiclassical method of Caldeira-Leggett theory: the depinning rate at a temperature T , $\Gamma(T) = A(T) \exp[-B(T)]$, is obtained by performing the imaginary-time path integral³⁸

$$\int D\{x\} \int D\{y\} \exp \left[\frac{-1}{\hbar} \oint d\tau \mathcal{L}_E \right] \quad (4)$$

over $\vec{X}_\tau \equiv \vec{X}(\tau, z)$ trajectories, which are periodic in τ with period $\hbar/k_B T$. Notice that $\tau = it$ is the imaginary time and \mathcal{L}_E is the Euclidean version of Eq. (3). That is,

$$\mathcal{L}_E[\tau, \vec{X}_\tau, \dot{\vec{X}}_\tau, \partial_z \vec{X}_\tau] = \int_0^L dz \left\{ -i \dot{\vec{X}}_\tau \cdot \vec{A}_{\rho_G} + \omega(\vec{X}_\tau, \partial_z \vec{X}_\tau) \right\}, \quad (5)$$

The energy density $\omega_1(\vec{X}_\tau)$ splits into the sum of three terms: The first one, $\omega_{XY}(\vec{X}_\tau)$, represents the sum of the magnetostatic and exchange contributions in the z -cross-section, whose dependence on the vortex core coordinates is $\omega_{XY}(\vec{X}_\tau) \sim \vec{X}_\tau^2$ for small displacements²⁴. The second term, $\omega_{dep}(\vec{X}_\tau)$, represents the pinning energy density associated to the line defect. Recent experimental works have reported an even quartic dependence of pinning potentials on the VC coordinates for small displacements in permalloy rings³⁹. Consequently, it is legitimate to take the following functional dependence for the sum of both terms:

$$(\omega_{XY} + \omega_{dep})(\vec{X}_\tau) = \frac{1}{2} \kappa (x_\tau^2 + y_\tau^2) - \frac{1}{4} \beta p_4(x_\tau, y_\tau) \quad (6)$$

where (κ, β) are the parameters of our model and $p_4(x, y)$ is a linear combination of monomials of degree four on variables x and y . The last term is the Zeeman energy density, which is given by²⁴ $\omega_Z(\vec{X}_\tau) = -\mu [\hat{z} \times \vec{H}_{in}] \cdot \vec{X}_\tau$ -with $\mu = (2\pi/3) M_s n_v R$ - for small displacements. The latter correspond to the application of a weak in-plane magnetic field \vec{H}_{in} . In what follows, $\vec{H}_{in} = -H \hat{e}_y$ is applied along the Y direction.

The simple dependence $p_4(x_\tau, y_\tau) = x_\tau^4$ keeps the main features of the pinning potential (see Section V). We also neglect the elastic term $\frac{1}{2} \lambda \left(\frac{\partial y_\tau}{\partial z} \right)^2$. The assumptions made regarding the structure of the potential can affect

the values of factors of order unity but should not change our conclusions as to the magnitude of the effects studied in the manuscript. From all these considerations, the Lagrangian (5) becomes

$$\mathcal{L}_E[\tau, \vec{X}_\tau, \dot{\vec{X}}_\tau, \partial_z \vec{X}_\tau] = \int_0^L dz \left\{ -i\rho_G y_\tau \dot{x}_\tau - \mu h x_\tau + \frac{\kappa}{2} x_\tau^2 + \frac{\kappa}{2} y_\tau^2 - \frac{\beta}{4} x_\tau^4 + \frac{\lambda}{2} \left(\frac{\partial x_\tau}{\partial z} \right)^2 \right\} \quad (7)$$

Finally, Gaussian integration over y_τ reduces Eq. (4) to

$$\int D\{x\} \exp \left[\frac{-1}{\hbar} \oint d\tau \mathcal{L}_{E,eff} \right] \quad (8)$$

with

$$\mathcal{L}_{E,eff}[\tau, x_\tau, \dot{x}_\tau, \partial_z x_\tau] = \int_0^L dz \left\{ \frac{1}{2} \left(\frac{\rho_G^2}{\kappa} \right) \dot{x}_\tau^2 - \mu h x_\tau + \frac{\kappa}{2} x_\tau^2 - \frac{\beta}{4} x_\tau^4 + \frac{\lambda}{2} \left(\frac{\partial x_\tau}{\partial z} \right)^2 \right\} \quad (9)$$

Within the framework of the Caldeira-Leggett theory⁴⁰, dissipation is taken into account by adding a term

$$\frac{\eta}{4\pi} \int_0^L dz \oint d\tau \int_{\mathbb{R}} d\tau_1 \frac{(x_\tau(\tau, z) - x_\tau(\tau_1, z))^2}{(\tau - \tau_1)^2} \quad (10)$$

to the action of Eq. (8). The dissipative constant η is related to the damping of the magnetic vortex core³⁸ and Ref. 26 shows that $\eta \simeq 3\alpha_{LLG}|\rho_G|$, with α_{LLG} being the Gilbert damping parameter. Introducing dimensionless variables $\bar{\tau} = (\kappa/\sqrt{2}|\rho_G|)\tau$, $\bar{z} = (\kappa/2\lambda)^{1/2}z$ and $u = (2\beta/\kappa)^{1/2}x_\tau$, the depinning exponent becomes

$$B(T, h) = \frac{|\rho_G|\sqrt{\lambda\kappa}}{2\hbar\beta} \int d\bar{z} \oint d\bar{\tau} \left[\frac{1}{2} \dot{u}^2 + \frac{1}{2} (u')^2 + V(u, h) + \frac{\eta}{2\sqrt{2}\pi|\rho_G|} \int_{\mathbb{R}} d\bar{\tau}_1 \frac{(u(\bar{\tau}, \bar{z}) - u(\bar{\tau}_1, \bar{z}))^2}{(\bar{\tau} - \bar{\tau}_1)^2} \right] \quad (11)$$

where ' ' means derivative with respect to \bar{z} , $V(u, h) = -hu + u^2 - \frac{u^4}{4}$ is the normalized energy potential and $h = 2\sqrt{2\beta/\kappa^3}\mu H$. Let $u_0(h)$ be the relative minimum of V for a fixed value of h . We rescale the energy potential $V(u, h) \rightarrow V(u, h) := V(u_0(h) + u, h) - V(u_0(h), h)$ and the variable $u \rightarrow u_0(h) + u$ so that we obtain $V(u, h) = u^2 \left(\left(1 - \frac{3}{2}u_0^2(h) \right) - u_0(h)u - \frac{1}{4}u^2 \right)$.

III. INSTANTONS OF THE DISSIPATIVE 1+1 MODEL

Quantum depinning of the VC line is given by the evaluation of the depinning exponent (11) at the instanton solution of the Euler-Lagrange equations of motion of the 1+1 field theory described by Eq. (11). This gives

$$\ddot{u} + u'' - (2 - 3u_0^2(h))u + 3u_0(h)u^2 + u^3 - \frac{\sqrt{2}}{\pi} \frac{\eta}{|\rho_G|} \int_{\mathbb{R}} d\bar{\tau}_1 \frac{u(\bar{\tau}, \bar{z}) - u(\bar{\tau}_1, \bar{z})}{(\bar{\tau} - \bar{\tau}_1)^2} = 0 \quad (12)$$

with boundary conditions

$$u(-\Omega/2, \bar{z}) = u(\Omega/2, \bar{z}) \quad \bar{z} \in \mathbb{R} \\ \max_{\bar{\tau} \in [-\Omega/2, \Omega/2]} u(\bar{\tau}, \bar{z}) = u(0, \bar{z}) \quad \bar{z} \in \mathbb{R} \quad (13)$$

that must be periodic on the imaginary time $\bar{\tau}$ with the period $\Omega = \frac{\kappa}{\sqrt{2}|\rho_G|} \frac{\hbar}{k_B T}$. This equation cannot be solved analytically, so we must proceed by means of numerical methods. Notice that in the computation of instantons we can safely extend the integration over \bar{z} in Eq. (11) on the the whole set of real numbers.

A. Zero temperature

In this case we apply the 2D Fourier transform

$$\hat{u}(\omega, \theta) = \frac{1}{2\pi} \int_{\mathbb{R}^2} d\bar{\tau} d\bar{z} u(\bar{\tau}, \bar{z}) e^{i(\omega\bar{\tau} + \theta\bar{z})} \quad (14)$$

to Eq. (12) and obtain

$$\hat{u}(\omega, \theta) = \frac{1}{\omega^2 + \theta^2 + \sqrt{2}|\omega|\eta/|\rho_G| + 2 - 3u_0^2(h)} \left(\frac{3u_0(h)}{2\pi} \times \int_{\mathbb{R}^2} d\omega_1 d\theta_1 \hat{u}(\omega_1, \theta_1) \hat{u}(\omega - \omega_1, \theta - \theta_1) + \frac{1}{(2\pi)^2} \times \int_{\mathbb{R}^4} d^2\vec{\omega} d^2\vec{\theta} \hat{u}(\omega_2, \theta_2) \hat{u}(\omega_1 - \omega_2, \theta_1 - \theta_2) \hat{u}(\omega - \omega_1, \theta - \theta_1) \right) \quad (15)$$

which is an integral equation for \hat{u} . The depinning exponent (11) in the Fourier space becomes

$$B(T=0, h) = \frac{|\rho_G|\sqrt{\kappa\lambda}}{2\hbar\beta} \left[\int_{\mathbb{R}^2} d\omega d\theta \hat{u}(\omega, \theta) \hat{u}(-\omega, -\theta) \left(\left(1 - \frac{3}{2}u_0^2(h) \right) + \frac{\omega^2 + \theta^2}{2} + \frac{|\omega|}{\sqrt{2}} \frac{\eta}{|\rho_G|} \right) - \frac{u_0(h)}{2\pi} \int_{\mathbb{R}^4} d^2\vec{\omega} d^2\vec{\theta} \hat{u}(\omega_1, \theta_1) \hat{u}(\omega_2, \theta_2) \hat{u}(-\omega_1 - \omega_2, -\theta_1 - \theta_2) - \frac{1}{(4\pi)^2} \int_{\mathbb{R}^6} d^3\vec{\omega} d^3\vec{\theta} \hat{u}(\omega_1, \theta_1) \hat{u}(\omega_2, \theta_2) \hat{u}(\omega_3, \theta_3) \hat{u}(-\omega_1 - \omega_2 - \omega_3, -\theta_1 - \theta_2 - \theta_3) \right]. \quad (16)$$

The zero-temperature instanton is computed using an algorithm that is a field-theory extension of the algorithm introduced in Refs. 41, 42 for the problem of dissipative quantum tunneling of a particle: To begin with, we introduce the operator

$$O(\lambda, \alpha, \hat{u}(\omega, \theta), h) = \frac{1}{\omega^2 + \theta^2 + \sqrt{2}|\omega|\eta/|\rho_G| + 2 - 3u_0^2(h)} \times \left(\lambda \int_{\mathbb{R}^2} d\omega_1 d\theta_1 \hat{u}(\omega_1, \theta_1) \hat{u}(\omega - \omega_1, \theta - \theta_1) + \alpha \int_{\mathbb{R}^4} d^2\vec{\omega} d^2\vec{\theta} \hat{u}(\omega_2, \theta_2) \hat{u}(\omega_1 - \omega_2, \theta_1 - \theta_2) \hat{u}(\omega - \omega_1, \theta - \theta_1) \right). \quad (17)$$

which generalizes the integral operator from Eq. (15). Notice that the equation of motion for the instanton in the Fourier space becomes $\hat{u}(\omega, \theta) = O(3u_0(h)/2\pi, 1/(2\pi)^2, \hat{u}(\omega, \theta), h)$. Secondly, it is important to point out the *scaling property* of this operator because it will be used in the computation of Eq. (16): Given any triplet $(\lambda_0, \alpha_0, \hat{u}_0(\omega, \theta))$ satisfying the identity (15), so will any other triplet $(\lambda_1, \alpha_1, \hat{u}_1(\omega, \theta))$ provided that

$$\hat{u}_1(\omega, \theta) = \chi \hat{u}_0(\omega, \theta) \quad (18)$$

$$\lambda_1 = \lambda_0/\chi \quad (19)$$

$$\alpha_1 = \alpha_0/\chi^2, \quad (20)$$

where χ is a constant. This means that if we are able to find a solution $(\lambda_1, \alpha_1, \hat{u}_1(\omega, \theta))$ for arbitrary parameters (λ_1, α_1) , then we can obtain the solution corresponding to the pair (λ_0, α_0) simply by rescaling $\hat{u}_1(\omega, \theta)$ by a factor $\chi = \lambda_1/\lambda_0$ as long as $(\lambda_1/\lambda_0)^2 = \alpha_1/\alpha_0$ is verified.

The algorithm consists of the following steps:

1. Start with an initial $(\lambda_0, \alpha_0, \hat{u}_0(\omega, \theta))$.
2. Let $\hat{u}_1(\omega, \theta) = O(\lambda_0, \alpha_0, \hat{u}_0(\omega, \theta), h)$.
3. Calculate $\lambda_1 = \lambda_0/\chi^2, \alpha_1 = \alpha_0/\chi^3$, where $\chi = \hat{u}_1(\vec{0})/\hat{u}_0(\vec{0})$.
4. Find $\hat{u}_2(\omega, \theta) = O(\lambda_1, \alpha_1, \hat{u}_1(\omega, \theta), h)$.
5. Repeat steps (2)-(4) until the successive difference satisfies a preset convergence criterion.

The output is the triplet $(\lambda_n, \alpha_n, \hat{u}_n(\omega, \theta))$. The final step consists of rescaling \hat{u}_n to obtain the solution corresponding to the pair $(\lambda, \alpha) = (3u_0(h)/2\pi, 1/(2\pi)^2)$: from the scaling property we know that the rescaling rules of the λ - and α - terms of Eq. (15) are different. Thus, to obtain an accurate approximation of the instanton solution we have split $\hat{u}(\omega, \theta)$ into the sum of two functions $\hat{u}_1(\omega, \theta)$ and $\hat{u}_2(\omega, \theta)$ in the above algorithm, and calculated their next iteration by means of the λ -term, respectively the α -term of the operator (17). Finally, we rescale \hat{u}_1 by a factor $2\pi\lambda_n/3u_0(h)$ and \hat{u}_2 by a factor $2\pi\sqrt{\alpha_n}$. The depinning rate is calculated evaluating Eq. (16) at this solution.

B. Non-zero temperature

In the $T \neq 0$ case, taking into account the finite periodicity on $\vec{\tau}$ we consider a solution of the type

$$u(\vec{\tau}, \vec{z}) = \sum_{n \in \mathbb{Z}} u_n(\vec{z}) e^{-i\omega_n \vec{\tau}} \quad (21)$$

with $\omega_n = \frac{2\pi n}{\Omega}$ for all $n \in \mathbb{Z}$. Introducing this functional dependence into Eq. (12) and applying a 1D Fourier transform we obtain

$$\hat{u}_n(\theta) = \frac{1}{\omega_n^2 + \theta^2 + \sqrt{2}|\omega_n|\eta/|\rho_G| + 2 - 3u_0^2(h)} \times \left(\frac{3u_0(h)}{\sqrt{2\pi}} \sum_{p \in \mathbb{Z}} \int_{\mathbb{R}} d\theta_1 \hat{u}_p(\theta_1) \hat{u}_{n-p}(\theta - \theta_1) + \frac{1}{2\pi} \sum_{p, q \in \mathbb{Z}} \int_{\mathbb{R}^2} d^2\vec{\theta} \hat{u}_p(\theta_2) \hat{u}_q(\theta_1 - \theta_2) \hat{u}_{n-p-q}(\theta - \theta_1) \right) \quad (22)$$

which is an integral equation for the set $\{\hat{u}_n\}_{n \in \mathbb{Z}}$ of Fourier coefficients. The depinning exponent (11) in the Fourier space becomes

$$B(T > 0, h) = \frac{|\rho_G| \sqrt{\kappa\lambda}}{2\hbar\beta} \left[\sum_{n \in \mathbb{Z}} \int_{\mathbb{R}} d\theta \hat{u}_n(\theta) \hat{u}_{-n}(-\theta) \left(\left(1 - \frac{3}{2} u_0^2(h) \right) + \frac{\omega_n^2 + \theta^2}{2} + \frac{|\omega_n|}{\sqrt{2}} \frac{\eta}{|\rho_G|} \right) - \frac{u_0(h)}{\sqrt{2\pi}} \sum_{n, m \in \mathbb{Z}} \int_{\mathbb{R}^2} d^2\vec{\theta} \hat{u}_n(\theta_1) \hat{u}_m(\theta_2) \hat{u}_{-n-m}(-\theta_1 - \theta_2) - \frac{1}{8\pi} \sum_{n, m, l \in \mathbb{Z}} \int_{\mathbb{R}^3} d^3\vec{\theta} \hat{u}_n(\theta_1) \hat{u}_m(\theta_2) \hat{u}_l(\theta_3) \hat{u}_{-n-m-l}(-\theta_1 - \theta_2 - \theta_3) \right] \Omega \quad (23)$$

The numerical algorithm is analogous to the one used in the zero-temperature case, but taking into account the rescaling of $\{\hat{u}_p^1\}_{p \in \mathbb{Z}}$ by a factor $\sqrt{2\pi}\lambda_n/3u_0(h)$ and $\{\hat{u}_p^2\}_{p \in \mathbb{Z}}$ by a factor $\sqrt{2\pi}\alpha_n$ in the last step of the calculations.

Fig. 2 shows the normalized action $\bar{B}(T) = \frac{2\hbar\beta}{|\rho_G| \sqrt{\kappa\lambda}} B(T)$ as a function of Ω at different values of the parameter h . In the simulations we have taken the standard value $\alpha_{LLG} = 0.008$ for bulk Permalloy²⁶.

IV. CROSSOVER TEMPERATURE

The crossover temperature determines the transition from thermal to quantum tunneling relaxation regimes. It can be computed by means of theory of phase transitions⁴³: above T_c , the instanton solution minimizing Eq. (11) is a $\vec{\tau}$ -independent function $u(\vec{\tau}, \vec{z}, h) =$

FIG. 2: (Color online) Temperature dependence of the depinning rate: normalized action $\frac{2\hbar\beta}{|\rho_G|\sqrt{\kappa\lambda}}B(T)$ versus Ω at different values of the parameter h .

$\bar{u}_0(\bar{z}, h)$, whereas just below T_c the instanton solution can be split into the sum of \bar{u}_0 and a small perturbation depending on $\bar{\tau}$,

$$u(\bar{\tau}, \bar{z}, h) = \bar{u}_0(\bar{z}, h) + \bar{u}_1(\bar{z}, h) \cos\left(\frac{2\pi}{\Omega}\bar{\tau}\right) \quad (24)$$

The depinning exponent (11) is proportional to

$$\int_{\mathbb{R}} d\bar{z} \Phi(\bar{z}; \bar{u}_1, \bar{u}'_1) \quad (25)$$

where Φ is the spatial action density. Introducing the expansion (24) into Eq. (11) we obtain the following expansion

$$\begin{aligned} \Phi(\bar{z}; \bar{u}_1, \bar{u}'_1) &= \left[\frac{1}{2}(\bar{u}'_0)^2 + V(\bar{u}_0, h) \right] \Omega + \\ &\frac{\Omega}{4}(\bar{u}'_1)^2 + \Lambda \bar{u}_1^2 + O(4) \end{aligned} \quad (26)$$

with

$$\Lambda = \frac{\Omega}{4}V''(\bar{u}_0, h) + \frac{\pi^2}{\Omega} + \frac{\pi}{\sqrt{2}}\frac{\eta}{|\rho_G|} \quad (27)$$

If $\Lambda > 0$ the only pair (\bar{u}_1, \bar{u}'_1) minimizing Φ is $\bar{u}_1 \equiv 0$. The crossover temperature is then defined by the equation $\min_{\bar{z} \in \mathbb{R}} \Lambda = 0$, that is

$$\frac{\Omega_c}{4} \min_{\bar{z} \in \mathbb{R}} V''(\bar{u}_0, h) + \frac{\pi^2}{\Omega_c} + \frac{\pi}{\sqrt{2}}\frac{\eta}{|\rho_G|} = 0 \quad (28)$$

The equation of motion for a $\bar{\tau}$ -independent instanton is

$$\bar{u}_0'' - (2 - 3u_0^2(h))\bar{u}_0 + 3u_0(h)\bar{u}_0^2 + \bar{u}_0^3 = 0 \quad (29)$$

with boundary conditions: $\bar{u}_0 \rightarrow 0$ at $|\bar{z}| \rightarrow \infty$ and $\bar{u}_0(0, h) = -2u_0(h) + \sqrt{4 - 2u_0^2(h)} \equiv w(h)$, which is the width of the potential. Consequently,

$$\begin{aligned} \min_{\bar{z} \in \mathbb{R}} V''(\bar{u}_0(\bar{z}, h), h) &= \min_{\bar{u}_0 \in [0, w(h)]} V''(\bar{u}_0, h) = \\ &\min_{\bar{u}_0 \in [0, w(h)]} \left\{ (2 - 3u_0^2(h)) - 6u_0(h)\bar{u}_0 - 3\bar{u}_0^2 \right\} = \\ &-10 + 3u_0^2(h) + 6u_0(h)\sqrt{f(h)} \end{aligned} \quad (30)$$

with $f(h) = 4 - 2u_0^2(h)$. Solving the quadratic equation for T_c given by Eq. (28) we obtain the crossover temperature

$$T_c(h) = \frac{\hbar\kappa}{4\pi k_B |\rho_G|} \left[\sqrt{8 + 3f(h) - 12u_0(h)\sqrt{f(h)} + \frac{\eta^2}{\rho_G^2} \frac{\eta}{|\rho_G|}} \right] \quad (31)$$

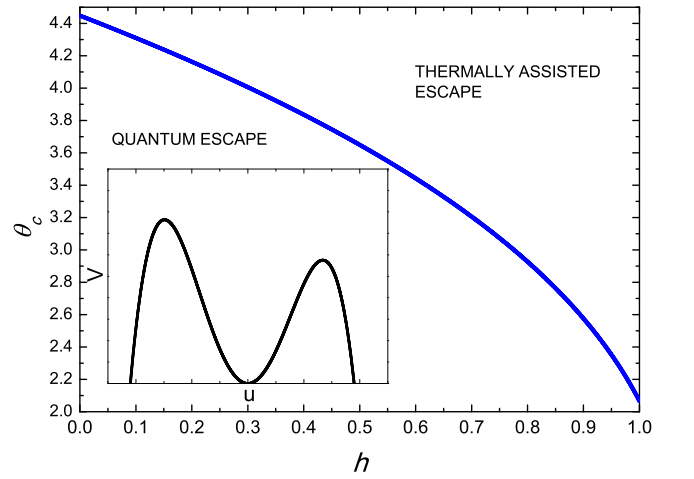

FIG. 3: (Color online) Field dependence of the dimensionless crossover temperature $\theta_c = \frac{4\pi k_B |\rho_G|}{\hbar\kappa} T_c$. (Inset) Sketch of the potential $V(u, h = 0.1)$.

Figure 3 shows the dependence of the dimensionless crossover temperature $\theta_c = \frac{4\pi k_B |\rho_G|}{\hbar\kappa} T_c$ on the generalized magnetic field h .

V. DISCUSSION AND PARAMETERS FITTING

For a given value of the generalized field h , in Fig. 2 we clearly distinguish two regimes in the dependence of the normalized action on Ω : above $\Omega_c(h)$ the normalized action tends to a constant value, whereas below it the normalized action is linear with Ω . Notice that the transition from the linear to the constant regime is smooth (that is, of second-order type). Above T_c the depinning rate becomes

$$B(T > T_c, h) = \frac{|\rho_G|\sqrt{\lambda\kappa}}{2\hbar\beta} \int d\bar{z} \left[\frac{1}{2}(\bar{u}'_0)^2 + V(\bar{u}_0, h) \right] \Omega \quad (32)$$

with \bar{u}_0 being the $\bar{\tau}$ -independent instanton. By means of Eq. (29) this expression can be rewritten as³⁸

$$B(T > T_c, h) = \frac{|\rho_G| \sqrt{\lambda \kappa}}{2\hbar\beta} \left[2\sqrt{2} \int_0^{w(h)} d\bar{u}_0 \sqrt{V(\bar{u}_0, h)} \right] \Omega \quad (33)$$

and, consequently, the slope of the normalized action $\bar{B}(\Omega)$ is equal to $2\sqrt{2} \int_0^{w(h)} d\bar{u}_0 \sqrt{V(\bar{u}_0, h)}$, which can be evaluated analytically. At all values of the generalized field h , the numerical slope calculated from Fig. 2 coincides with the analytical one within the numerical error of our simulations. This is indicative of the robustness of our algorithm.

Quantum effects reported in Ref. 22 can be understood as being plausibly due to the depinning from line defects present in the disk. The size of the defects needs to exceed the nucleation length in order to pin the VC, but not to be as long as the thickness of the disk. Pinning of extended parts of the VC line by line defects would be justified by the fact that linear defects provide the strongest pinning so that the VC line, or at least some segments of it, would naturally fall into such traps. Consequently, we can test out our model on the experimental results obtained in Ref. 22. The crossover temperature is relevant to the roughness of the fine-scale potential landscape due to linear defects at the bottom of the potential well created by the external and dipolar fields. Above T_c vortices diffuse in this potential by thermal activation, whereas below T_c they diffuse by quantum tunneling. This must determine the temperature dependence (independence) of the magnetic viscosity. T_c is, therefore, the measure of the fine-scale barriers due to linear defects. It can be measured experimentally and help to extract the width of the pinning potential.

Now we proceed to obtain estimates of the model parameters (κ, β) by fitting our model to experimental data: Figure 4 shows new magnetic relaxation measurements of permalloy disks in the vortex state from the remnant state to equilibrium (zero magnetization). The radius of these disks is $R = 0.75 \mu\text{m}$ and their thickness is $L = 95 \text{ nm}$ (subfig. 4a) and $L = 60 \text{ nm}$ (subfig. 4b). A concise description of the experimental set-up and sample preparation can be found in Ref. 22. Notice that for both samples the magnetization depends logarithmically on time during the relaxation process.

Magnetic viscosity of these relaxation measurements is computed by means of the formula³⁸:

$$S(T) = -\frac{1}{M_0} \frac{\partial M}{\partial \ln t}, \quad (34)$$

where M_0 is the initial magnetization point. That is, the viscosity at zero field is obtained computing the slopes of the normalized magnetization curves. Fig 5 shows the magnetic viscosity as a function of temperature for both samples. Below $T_c = 6 \text{ K}$, magnetic viscosity reaches a plateau with non-zero value. Above T_c , magnetic viscosity increases up to a certain temperature, from which it

FIG. 4: (Color online) Relaxation measurements of magnetic vortices from the remnant state to equilibrium for samples $(L, R) = (95, 750) \text{ nm}$ (subfig (a)) and $(L, R) = (60, 750) \text{ nm}$ (subfig (b)).

FIG. 5: (Color online) Magnetic viscosity versus temperature for both samples. The arrows point towards the non-zero value of the plateaus.

decreases again. The existence of the plateau is the evidence of underbarrier quantum tunneling phenomena. The increase of viscosity with temperature above the crossover temperature is due to thermal activation over the pinning barriers. Finally, the drop of the magnetic viscosity is in agreement with the loss of magnetic irreversibility in our systems²². On the other hand, the fact that the crossover temperature T_c is independent of the thickness of the disks upholds our hypothesis that just a small portion of the VC line takes part in the tunneling process via an elastic deformation.

Notice that the depinning rate should not exceed 30 – 40 in order for the tunneling to occur on a reasonable time scale. The estimates of the parameters (κ, β) are obtained fitting Eq. (31) and Eq. (16) to the values $T_c \sim 6$ K, respectively $B(T = 0, h = 0) \sim 30$ at zero field. Considering the experimental values $A = 1.3 \cdot 10^{-11}$ J/m and $M_s = 7.5 \cdot 10^5$ A/m for permalloy, we obtain

$$\kappa \sim 5.9 \cdot 10^7 \text{ J/m}^3, \quad \beta \sim 6.9 \cdot 10^{27} \text{ J/m}^5 \quad (35)$$

from which we can determine the width of the quartic potential, $w = \sqrt{2\kappa/\beta} \sim 0.13$ nm. This value is compatible with the width of the potential provided by a linear

dislocation

In conclusion, we have studied quantum escape from a line defect of the VC line in a disk made of a soft ferromagnetic material. In the case of permalloy disks, experimental results let us conclude that the depinning process occurs in steps about 0.13 nm, which corresponds to the width of the energy potential.

VI. ACKNOWLEDGMENTS

The authors acknowledge V. Novosad for providing the samples discussed in the paper and Grup de Dinàmica Financera de la UB for the use of their computing facilities.
