(Dated: 12 September 2014)

The upper critical field H_{c2} and its anisotropy are calculated for order parameters with line nodes at equators, $k_z = 0$, of the Fermi surface of uniaxial superconductors. It is shown that characteristic features found in Fe-based materials – a nearly linear $H_{c2}(T)$ in a broad T domain, a low and increasing on warming anisotropy $\gamma_H = H_{c2,ab}/H_{c2,c}$ – can be caused by competing effects of the equatorial nodes and of the Fermi surface anisotropy. For certain material parameters, $\gamma_H(T) - 1$ may change sign on warming in agreement with recorded behavior of FeTeS system. It is also shown that the anisotropy of the penetration depth $\gamma_\lambda = \lambda_c/\lambda_{ab}$ decreases on warming to reach γ_H at T_c in agreement with data available. For some materials $\gamma_\lambda(T)$ may change on warming from $\gamma_\lambda > 1$ at low Ts to $\gamma_\lambda < 1$ at high Ts.

Iron-based superconductors are layered compounds with nearly cylindrical Fermi surfaces which at first sight should have lead to high anisotropies of the upper critical field and the London penetration depth. This, however, is not the case. Most of these compounds have relatively low values of $\gamma_H = H_{c2,ab}/H_{c2,c}$ that *increase on warming* [1] and in some materials even change from $\gamma_H < 1$ at low temperatures to $\gamma_H > 1$ at high Ts [2, 3]. The anisotropy of the London penetration depth is also low but *decreases on warming* [4]. Originally, such behavior was attributed to multi-band physics similar to that of MgB₂ [5]. However, in MgB₂, $\gamma_H(T)$ decreases on warming whereas $\gamma_\lambda(T)$ increases, just the opposite to Fe-based materials.

Recently, the increasing $\gamma_H(T)$ had been associated with the order parameter modulated along the c-axis [6] even in a single-band scenario, so that multi-band effects *per se* are not necessary to explain the observed beahvior of $H_{c2}(T)$ and $\lambda(T)$. It is also known that some Fe-based materials have gap nodes and there are models suggesting equatorial, $k_z = 0$, line nodes [8]. Such gap structure is seen in the ARPES data on BaFe₂(As_{0.7}P_{0.3})₂ [9, 10] and was also explored for other unconventional superconductors, for example, Sr₂RuO₄ to understand anisotropic thermal conductivity [11, 12].

Here we show that the competing effects of equatorial nodes and the Fermi surface anisotropy might be responsible for the observed behavior of H_{c2} in these materials. Moreover, equatorial line nodes cause the anisotropy of the London penetration depth, γ_{λ} , to *decrease on warming*, the feature seen in a number of materials for which data on λ -anisotropy are available [4]. The interplay of the Fermi surface effects and those due to line nodes can result in the temperature dependent sign of $\gamma_{\lambda} - 1$, the prediction to be verified. In particular this interplay causes the in-plane superfluid density to change with temperature in a "d-wave-like" fashion (linear at low Ts) while being rather flat at low Ts for the c direction.

Studying the orbital $H_{c2}(T)$, we employ a version of Helfand-Werthamer (HW) theory [13] generalized for clean anisotropic superconductors [6]. It is based on Eilenberger quasi-classical formulation of the superconductivity [14] with a weak-coupling separable potential $V(,k') = V_0 \Omega(k) \Omega(k')$ and the order parameter in the form $\Delta = \Psi(\mathbf{r}, T) \Omega(\mathbf{k})$, k is the Fermi momentum [15]. $\Omega(\mathbf{k})$ determines the k dependence of Δ and is normalized so that the average over the Fermi surface $\langle \Omega^2 \rangle = 1$. This popular approximation works well for one band materials with anisotropic coupling and can be generalized to a multi-band case [6].

Within this theory, $H_{c2,c}$ along the *c* axis of uniaxial crystals is found by solving an equation [6]:

$$\ln t = 2h_c \int_0^\infty s \, \ln \tanh(st) \left\langle \Omega^2 \mu_c e^{-\mu_c h_c s^2} \right\rangle ds \,, \tag{1}$$

$$h_c = H_{c2,c} \frac{\hbar^2 v_0^2}{2\pi \phi_0 T_c^2}, \ \mu_c = \frac{v_x^2 + v_y^2}{v_0^2}, \ v_0^3 = \frac{2E_F^2}{\pi^2 \hbar^3 N(0)}.$$
 (2)

Here, $t = T/T_c$, v_x, v_y are Fermi velocities in the a, b plane, E_F is the Fermi energy, N(0) is the total density of states at the Fermi level per spin, the velocity $v_0 = v_F$ for the isotropic case, and $\langle ... \rangle$ stands for the Fermi surface average.

In principle, Eq. (1) can be used to evaluate $h_c(t)$ for any order parameter anisotropy (any Ω) and any Fermi surface (any μ_c). Both Ω and μ_c enter Eq. (1) under the sign of the Fermi surface averaging and one does not expect fine details of Fermi surface to affect strongly the $H_{c2,c}(T)$ shape. For this reason, describing Fermi surface shapes, we focus on a simplest version of Fermi spheroids, for which the averaging is a well defined analytic procedure, see e.g. [6, 7].

In general, Eq. (1) can be solved numerically, but if $T \to T_c$, the result is exact [6]:

$$h_c = \frac{8(1-t)}{7\zeta(3) \left< \Omega^2 \mu_c \right>},\tag{3}$$

where $\zeta(3) \approx 1.202$. For the isotropic case $\Omega = 1$, $\langle \mu_c \rangle = 2/3$, and one reproduces the HW slope near T_c in the clean limit.

At T = 0, Eq. (1) was shown to yield [6]:

$$h_c(0) = e^{-C - \langle \Omega^2 \ln \mu_c \rangle}, \qquad (4)$$

where $C \approx 0.577$ is the Euler constant. Hence, we obtain the HW ratio,

$$h_c^*(0) = \frac{H_{c2,c}(0)}{T_c H_{c2,c}'(T_c)} = \frac{h_c(0)}{h_c'(1)} = \frac{7\zeta(3)}{8e^C} \langle \Omega^2 \mu_c \rangle e^{-\langle \Omega^2 \ln \mu_c \rangle}; \quad (5)$$

 $H'_{c2,c}(T_c) \equiv dH_{c2,c}/dT$ at T_c and $h'_c(1) = (dh_c/dt)_{t=1}$. For the isotropic case this gives the clean limit HW value $h_c^*(0) = 7\zeta(3)/48e^{C-2} = 0.727$.

Thus, both the order parameter symmetry and the Fermi surface affect $h_c^*(0)$. However, as shown at the right panel of Fig. 1, for s-wave order parameters on Fermi spheroids, $h_c^*(0)$ remains close to 0.7 for all ratios of the spheroid semi-axes [6]. We also note that $h_c^*(0)$ is nearly insensitive to the non-magnetic transport scattering, but it decreases fast in the presence of pair breaking to reach 0.5 for the strong T_c suppression [16].

To study how the order parameter anisotropy affects $H_{c2,c}(T)$ and $h_c^*(0)$, we first consider the case of the Fermi sphere. We are interested in k_z dependent order parameters, that on the Fermi sphere implies that Ω depends on the polar angle θ . We model equatorial nodes by setting $\Omega = \Omega_0 \cos^n \theta$. Near the "equator" at $\theta = \pi/2$, $|\Delta|$ behaves as $|\theta - \pi/2|^n$. Clearly, the bigger the power n, the wider is the equatorial belt where the order parameter is close to zero (we will call the power n the "node order").

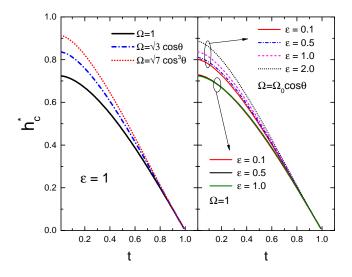

FIG. 1. (Color online) $h_c^*(t)$ for various Fermi surfaces and order parameters. Left panel: Fermi sphere and $\Omega = \sqrt{2n+1}\cos^n\theta$ with n = 0, 1, 3. One sees that equatorial nodes cause a substantial increase of $h_c^*(0)$ and widen the domain of nearly linear behavior of $h_c^*(t)$. Note also a slight positive curvature at high Ts for n = 1, 3. Right panel: the lower group of three nearly coincident curves are for s-wave order parameter on a Fermi sphere and two prolate spheroids. The upper group is for $\Omega \propto \cos \theta$ showing clearly that $h_c^*(0)$ increases with increasing ϵ , the ratio of effective masses m_c/m_{ab} (of squared spheroid's semi-axes).

It is readily shown that

$$\Omega_0 = \sqrt{2n+1}, \qquad \left\langle \Omega^2 \mu_c \right\rangle = \frac{2(2n+1)}{4n^2 + 8n + 3}, \\ \left\langle \Omega^2 \ln \mu_c \right\rangle = -\mathbf{C} - \psi \left(n + 3/2 \right), \qquad (6)$$

where ψ is the digamma function. Thus, we have:

$$h_c^*(0) = \frac{7\zeta(3)}{4} \frac{2n+1}{4n^2+8n+3} e^{\psi(n+3/2)}, \qquad (7)$$

i.e, $h_c^*(0)$ increases with increasing n. On the other hand, a larger $h_c^*(0)$ translates to a broader temperature range where h(t) is close to being linear. We then expect the curve $H_{c2,c}(T)$ to have an extended linear domain for increasing n. To check this we turn to the full temperature dependence $h_c(t)$ by solving Eq. (1) numerically. The results are shown in the left panel of Fig. 1. We estimate that $h_c^*(t)$ deviates from the straight line $h_c^{r'}(1)(t-1)$ by less than 1% in the domain t > 0.6 for n = 0 (the s-wave), t > 0.4 for n = 1, and t > 0.2 for n = 3. Therefore, increasing the node order causes "straightening" of $H_{c2,c}(T)$ observed in pnictides [17] and some other materials [18].

Performing calculations for Fermi spheroids, one should evaluate properly Fermi surface averages. Details of this procedure were worked out in [6, 7]. Examples of $h_c^*(t)$ so obtained for a few values ϵ , the squared ratio of the semi-axes, are given in the right panel of Fig. 1.

Similar to Eq. (1) for $H_{c2,c}(T)$, one can obtain an equation for $H_{c2,ab}(T)$, or directly for the anisotropy parameter $\gamma_H = H_{c2,ab}/H_{c2,c}$ [6]. In fact, $\gamma_H(t)$ satisfies Eq. (1)

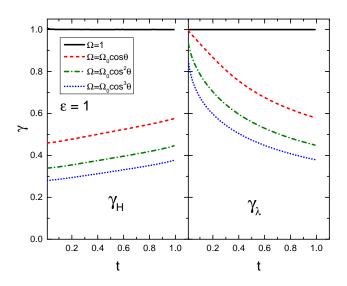

FIG. 2. (Color online) $\gamma_H = H_{c2,ab}/H_{c2,c}$ and $\gamma_{\lambda} = \lambda_c/\lambda_{ab}$ for the Fermi sphere and order parameters shown in the legend. Thus, the values of both γ_H and γ_{λ} are suppressed by equatorial line nodes; the suppression is stronger for higher node orders. Besides, the nodes cause $\gamma_H(T)$ to increase on warming, whereas γ_{λ} decreases with increasing T, the feature reported, e.g., for Nd-1111 [4].

in which, however, $h_c(t)$ is now known and μ_c is replaced with

$$\mu_b = \frac{v_x^2 + \gamma_H^2 v_z^2}{v_0^2} \,. \tag{8}$$

The left panel of Fig. 2 shows $\gamma_H(t)$ for equatorial line nodes with n = 1, 2, 3. One sees that for this type of nodes on a sphere (i) $\gamma_H < 1$, i.e., $H_{c2,c} > H_{c2,ab}$ and (ii) γ_H increases on warming, the feature ubiquitous for the Fe-based materials.

On the other hand, in materials such as pnictides, the Fermi surfaces are warped cylinders and $H_{c2,ab} > H_{c2,c}$; $\gamma_H(t) > 1$ but it is not large. Qualitatively, one can model these Fermi surfaces as prolate spheroids, for which it was shown that $\gamma_H > 1$ for s-wave order parameters [6, 7]. Thus, effect of equatorial nodes on γ_H is the opposite to that of prolate Fermi surfaces. It is of interest therefore to study order parameters $\propto \cos^n \theta$ on prolate spheroids. Figure 3 shows examples for spheroids with

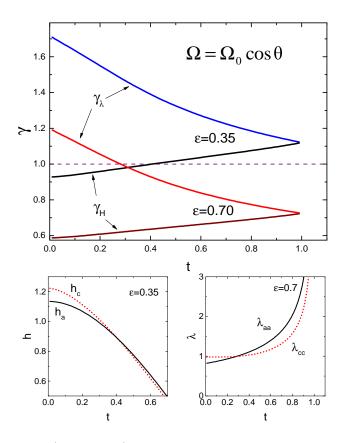

FIG. 3. (Color online) The upper panel: anisotropy parameters γ_{λ} and γ_{H} for the order parameter $\propto \cos\theta$ for two spheroidal Fermi surfaces $\epsilon = 0.35$ and 0.70. The lower left panel shows the crossing of $h_c(t)$ and $h_a(t)$ near $t^* = 0.4$ for $\epsilon = 0.35$. The lower right panel shows the crossing of $\lambda_{aa}(t)$ and $\lambda_{cc}(t)$ near $t^* = 0.3$ for $\epsilon = 0.70$; both $\lambda_{aa}(t)$ and $\lambda_{cc}(t)$ are in units of $c/ev_0\sqrt{2\pi N(0)}$. Note the linear temperature dependence of λ_{aa} at low Ts and a flat "s-wave-like" behavior of λ_{cc}

 $\epsilon = 0.35$ and 0.70 and the order parameter $\propto \cos \theta$. Remarkably, for $\epsilon = 0.35$, $\gamma_H - 1$ changes sign near $t^* \approx 0.4$ so that $h_a < h_c$ for t < 0.4 and otherwise at higher temperatures.

We now turn to the London penetration depth. The inverse tensor of squared penetration depth for the general anisotropic clean case reads [19, 20]:

$$(\lambda^2)_{ik}^{-1} = \frac{16\pi^2 e^2 N(0)T}{c^2} \sum_{\omega>0} \left\langle \frac{\Delta^2 v_i v_k}{\beta^3} \right\rangle.$$
(9)

Here $\Delta = \Psi \Omega$, $\beta = \sqrt{\Delta^2 + \hbar^2 \omega^2}$, and $\Psi(T)$ satisfies the self-consistency equation:

$$-\ln t = \sum_{n=0}^{\infty} \left(\frac{1}{n+1/2} - \left\langle \frac{\Omega^2}{\sqrt{\psi^2 \Omega^2 + (n+1/2)^2}} \right\rangle \right) (10)$$

where $\psi = \Psi/2\pi T$.

Fermi velocities v, N(0), and $\Omega(k)$ are the input parameters for evaluation of λ_{aa} and λ_{cc} . N(0) is not needed if one is interested only in the ratio $\gamma_{\lambda} = \lambda_{cc}/\lambda_{aa}$:

$$\gamma_{\lambda}^{2} = \frac{\lambda_{aa}^{-2}}{\lambda_{cc}^{-2}} = \frac{\sum_{n} \left\langle \Omega^{2} v_{a}^{2} / \eta^{3/2} \right\rangle}{\sum_{n} \left\langle \Omega^{2} v_{c}^{2} / \eta^{3/2} \right\rangle},$$

$$\eta = \psi^{2} \Omega^{2} + (n + 1/2)^{2}. \tag{11}$$

In particular, this gives

$$\gamma_{\lambda}^{2}(0) = \frac{\langle v_{a}^{2} \rangle}{\langle v_{c}^{2} \rangle}, \qquad \gamma_{\lambda}^{2}(T_{c}) = \frac{\langle \Omega^{2} v_{a}^{2} \rangle}{\langle \Omega^{2} v_{c}^{2} \rangle}, \qquad (12)$$

showing that the order parameter anisotropy causes γ_{λ} to depend on T in a one-band situation [19, 21], the property commonly associated with many bands.

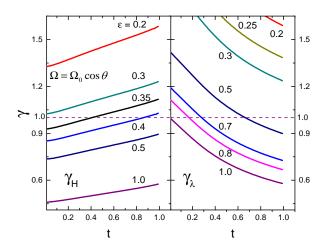

FIG. 4. (Color online) $\gamma_H(t)$ and $\gamma_\lambda(t)$ for the order parameter $\propto \cos \theta$ and the Fermi surface shapes ϵ indicated. One sees that $\gamma_H - 1$ changes sign in the domain $0.3 < \epsilon < 0.45$ whereas $\gamma_\lambda - 1$ in the region $0.45 < \epsilon < 1$.

The right panel of Fig. 2 shows γ_{λ} evaluated with the help of Eq. (11) for a Fermi sphere and $\Omega \propto \cos^n \theta$ with n = 0, 1, 2, 3. Hence, the equatorial line nodes cause $\gamma_{\lambda}(t)$ to decrease on warming, a behavior opposite to the increasing $\gamma_H(t)$ shown in the left panel. One also sees that the two anisotropy parameters meet at T_c , thus confirming consistency of the analytic and numerical procedures for evaluation of two physically different quantities: the high field $H_{c2}(T)$ at the second order phase transition and the low field penetration depth $\lambda(T)$.

The combined effect of the Fermi surface shape and of the order parameter $\Omega = \Omega_0 \cos \theta$ on both γ_λ and γ_H is shown on the upper panel of Fig. 3. The Fermi surface parameters ϵ are chosen to demonstrate interesting situations: while $\gamma_\lambda > 1$ at all temperatures for $\epsilon = 0.35$, the anisotropy γ_H , being less than unity under $t^* \approx 0.4$, exceeds 1 above this temperature. Such a behavior has been recorded for FeTeS [2, 3].

For $\epsilon = 0.7$ we have $\gamma_H < 1$ at all temperatures, whereas $\gamma_{\lambda} > 1$ at $t^* < 0.3$, but becomes less than unity above this temperature. The transverse magnetization of a material in the mixed state with such γ_{λ} placed in field tilted relative to principal crystal directions should change sign at t^* [22]. The same is true for the torque experienced by the crystal. In other words, the sign change of $\gamma_{\lambda} - 1$ can be detected by measuring the sign and angular dependence of the transverse magnetization or torque [23, 24].

Fig. 4 shows that temperatures t^* , at which $\gamma_H - 1$ and $\gamma_\lambda - 1$ change sign, vary as functions of the Fermi surface shape ϵ : with increasing ϵ these temperatures grow if one goes to a "less prolate" Fermi shapes.

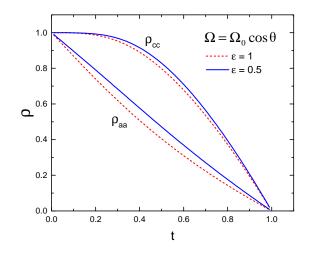

FIG. 5. (Color online) Superfluid densities $\rho_{aa} = \lambda_{aa}^2(0)/\lambda_{aa}^2(t)$ (the lower curves) and $\rho_{cc} = \lambda_{cc}^2(0)/\lambda_{cc}^2(t)$.

A popular quantity in analysis of penetration depth data is the superfluid density defined as λ^{-2} normalized on its value at T = 0. This quantity for two principal directions is plotted in Fig. 5 for an equatorial node, $\Omega = \Omega_0 \cos \theta$, on a sphere and spheroid with $\epsilon = 0.5$. Interestingly, the node presence results in $\rho_{aa}(t)$ qualitatively similar to the known d-wave linear low temperature behavior, whereas direct numerical check shows that $\rho_{cc} - 1 \propto t^3$. In fact, this behavior has been discussed considering properties of UBe₁₃ [25].

Interestingly, the order parameter $\Omega = \Omega_0 \cos \theta$ on prolate Fermi surfaces causes suppression of the specific heat jump at T_c , $\Delta C/C_n = 1.43/\langle \Omega^4 \rangle$ [26, 27]. For example, if $\epsilon = 0.1$, we estimate $\Delta C/C_n \approx 0.46$. Also, since for this type of order parameters $\langle \Omega \rangle = 0$, similar to the d-wave, T_c should be suppressed in the same manner by magnetic and non-magnetic impurities [28]. The data on electron irradiated crystals of Ba(Fe_{1-x}Ru_x)₂As₂ (x = 0.24) qualitatively support this statement, although multi-band Fermi surfaces complicate the picture [29].

Concluding, we reiterate that despite profound simplifications, such as single-band ellipsoidal Fermi surface and the order parameter with equatorial nodes, our model reproduces qualitative features of anisotropic $H_{c2}(T)$ and $\lambda(T)$ often seen in real materials, notably Fe-based superconductors. We do not claim that our model describes all properties of this diverse family of materials. We, however, point to potentially important role of competing equatorial nodes and Fermi surface anisotropy. Fine details of Fermi surfaces and order parameters enter the theory of $H_{c2}(T)$ and $\lambda(T)$ only as averages over the Fermi surface and thus do not justify formal complications of taking them into account. Also, as far as $H_{c2}(T)$ and $\lambda(T)$ are concerned, the singleand multi-band scenarios give similar results as shown in our previous study [6]. Here we reproduced a number of features ubiquitous for Fe-based superconductors, origin of which up to now was not even questioned. In particular, we find that the equatorial line node causes an extended domain of nearly linear $H_{c2}(T)$, anisotropy of which *increases on warming*. By studying competing effects of equatorial nodes and of the Fermi surface anisotropy we find that, nearly cylindrical Fermi shapes notwithstanding, materials with equatorial nodes can be only weakly anisotropic. For certain combinations of material parameters both $\gamma_H - 1$ and $\gamma_{\lambda} - 1$ may change sign on warming so that $H_{c2,ab} < H_{c2,c}$ at low Ts while $H_{c2,ab} > H_{c2,c}$ at high Ts. Similar situation may occur for the anisotropy of the London penetration depth, which can be probed by torque or transverse magnetization measurements in large fields. We also find that the nodes in question cause different T dependences of different components of the superfluid density tensor. These predictions call for experimental verification.

The authors are grateful to M. Tanatar, A. Kaminsky, S. Bud'ko, V. Taufor, P. Canfield, and P. Hirschfeld for interest and discussions. This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Division. The work was done at the Ames Laboratory, which is operated for the U.S. DOE by Iowa State University under contract DE-AC02-07CH11358.
