Abstract

We investigate the origin of the depolarization rates in ultrathin adsorbate-stabilized ferroelectric wires. By applying density functional theory calculations and analytic modeling, we demonstrate that the depolarization results from the leakage of charges stored at the surface adsorbates, which play an important role in the polarization stabilization. The depolarization speed varies with thickness and temperature, following several complex trends. A comprehensive physical model is presented, in which quantum tunneling, Schottky emission and temperature dependent electron mobility are taken into consideration. This model simulates experimental results, validating the physical mechanism. We also expect that this improved tunneling-Schottky emission model could be applied to predict the retention time of polarization and the leakage current for various ferroelectric materials with different thicknesses and temperatures.

I. INTRODUCTION

Spontaneous electric polarization makes perovskite-based oxides of great interest for application to nonvolatile memory devices [1, 2]. However, the polarization of ferroelectric materials may not be infinitely stable, and retention time is one of the key factors determining the performance of memory devices in nonvolatile technology. The proposed reasons for the polarization instability have included the depolarization field and the leakage current [3], whose effects become more significant as the oxide film gets thinner. Therefore, for successful technology application, the depolarization processes of nanoscale ferroelectric oxides must be better understood. Here, we report a combined experimental and theoretical investigation of the depolarization process of single-crystalline BaTiO₃ nanowires. We attribute the decay of polarization to the leakage of surface screening charge and propose an analytical model to explain the experimental decay rates.

A. Experimental background

The effects of the depolarization field on the stability of ferroelectricity in ultrathin materials was explored in BaTiO₃ nanowires by measuring the ferroelectric transition temperature as a function of the nanowire diameter in the range of 3–48 nm [4–7]. Positive ferroelectric domains were written perpendicular to the nanowire axis using a negative-bias voltage (−10 V) applied by a conductive scanning probe microscope cantilever tip (under ultrahigh vacuum conditions with a base pressure of 10^{−10} torr). The time evolution of the polarized domain was then monitored via time-resolved measurements of the local electric field, using non-contact electrostatic force microscopy (EFM). The writing and reading processes were done at various temperatures, starting from ≈ 393 K for thin nanowires (3–11 nm) and ≈ 418 K for the thicker ones (12–37 nm). The two sets of nanowires were progressively cooled down and retested to ≈ 308 K and ≈ 383 K were reached respectively. The Curie temperature T_C was defined as the highest temperature below which the polarization signal persists for a period longer than 200 hours. Experiments showed that T_C is inversely proportional to the diameter of the BaTiO₃ nanowire, in accord with standard models of depolarization field [8]. At several temperatures above T_C , the surface potential signals were measured during the process of polarization decay. The magnitude of surface potential was

62 fitted with the expression:

$$S(t) = S(0)e^{-k_d t} \quad (1)$$

63 where $S(t)$ is the potential at time t , which is proportional to the surface screening charge,
 64 and k_d is the decay rate, with the unit s^{-1} [9]. Here, we should note that experimentally it
 65 is found that the signals decay with time approximately (but not perfectly) exponentially.
 66 Despite the slight deviations, the decay rate k_d obtained from the data fitting is still an
 67 important physical parameter in describing the polarization decay speed. From the time
 68 evolution of the signal [4], we see that the bright circular signal faded without expansion,
 69 which means that the depolarization is a process of leakage or tunneling, rather than diffu-
 70 sion, of the surface screening charge. The observed decay rates k_d , which vary with nanowire
 71 thickness and temperature, are shown in FIG. 1 (please refer to the red circles). The raw
 72 data are also presented in supplementary material tables S1 and S2.

73

74 FIG. 1. Depolarization rates measured from experiments (red circles) and calculated from our
 75 model (blue squares).

76 The experimental data show three general trends: (1) The depolarization process is slow
 77 (several hours); (2) For any thickness, the decay rate k_d increases with temperature; (3) For
 78 thin nanowires (5–9 nm), the decay rate k_d changes with thickness dramatically. However,
 79 for thicker wires, k_d stays nearly constant at different thicknesses (21, 25, 37 and 48 nm).
 80 Our study aims at illustrating the physical essence of these trends.

B. Polarization stabilization

In recent years, many studies have investigated the dependence of polarization stabilization and leakage current on chemical environment, temperature, electrode material, and thickness [4, 8, 10–28]. From these studies, several basic principles could be drawn:

- (1) Surface polarization charge should be compensated by screening charge, in order to passivate the depolarization field and stabilize the ferroelectric distortion, or else the polarization would become unstable. The screening charge could be stored in surface electrodes or adsorbates [8, 10–18];
- (2) The polarization state of the material may lead to preferential adsorption of certain molecules on the surface [19–25];
- (3) The response of polarization with electric field or temperature is fast, but the time scale for dissipation of the surface screening charge is slow (hours or days) [26–28].

Based on the evidence above and the observations in our experiments, we propose that the physical process of depolarization in the BaTiO₃ nanowire experiment is as follows: after the polarization is written, surface adsorbates on the nanowire act as an electrode that stores screening charge and stabilizes the polarization [4]. For the case without external applied voltage and above T_C , the polarized state is not stable. But due to the stabilization of screening charge in the surface adsorbates, polarization in the nanowire still persists for some time. Screening charge leaks from the top electrode (surface adsorbate) to the other side of the BaTiO₃ nanowire (gold substrate). At the same time, polarization reduces along with the screening charge. This process is slow and takes hours.

In the following parts of this paper, support, analysis, and modeling of the physical processes described above are shown. In Section II, we use density functional theory to demonstrate the role of surface adsorption in surface charge screening. In Section III, analytical expressions describing leakage current leading to depolarization are developed. Finally, in Section IV, we present the results and discussion.

TABLE I. Löwdin population in the orbitals of OH adsorbed to BaO-terminated BaTiO₃.

	Polar	Non-polar
H 1s orbital	0.6121	0.5601
O 2s orbital	1.7315	1.8138
O 2p orbital	5.0719	4.5980
Net Charge	-0.4155	0.0289

II. DENSITY FUNCTIONAL THEORY CALCULATION

In order to construct a theory of the depolarization process, density functional theory calculations (DFT) are carried out to assess the role of surface molecular and atomic adsorbates. We investigate the OH molecule on BaO-terminated BaTiO₃ slabs, as OH is the predominant species found on oxide surfaces, as demonstrated by both infrared spectra and *ab initio* calculations [4, 29, 30].

Density functional theory (DFT) calculations with periodic boundary conditions were carried out using the QUANTUM-ESPRESSO plane-wave DFT code [31]. The exchange-correlation functional was approximated with the Perdew-Burke-Ernzerhof form of the generalized gradient scheme. Plane-wave cut-off energy of 50 Ry was used in all calculations. The pseudopotentials were generated using the OPIUM code following the norm-conserving designed non-local recipe [32, 33]. 1×1 five-unit-cell-thick BaTiO₃ slabs, separated by more than 20 Å of vacuum normal to the surface, were used to simulate the thin films. Additional dipole correction was added in the middle of the vacuum to further correct the spurious electric field interaction between periodic images. A k -point mesh of $6 \times 6 \times 1$ was used following the Monkhorst-pack sampling scheme [34]. Atomic forces were converged until a maximum threshold of 0.05 eV/Å per atom is reached.

As shown in FIG.2, from the relaxed structure, we see that the presence of the OH adsorbates enhances ferroelectricity at the positively polarized surface and maintains a characteristic ferroelectric displacement pattern throughout the film, which is consistent with the results in Ref. [4].

The density of states projected onto atomic orbitals (PDOS) was calculated to characterize the charge distribution on each atom. Results are shown in TABLE I, from which we see

FIG. 2. Relaxed structures for the BaTiO₃/OH systems acquired from DFT calculation. Green, blue, red and gray spheres represent barium, titanium, oxygen and hydrogen atoms respectively. (a) Polar system, OH is adsorbed at the surface. The dimension of the arrow is proportional to the layer rumpling (cation-oxygen displacement in the *z* direction.); (b) Non-polar structure, OH is far away from the surface of the BaTiO₃ surface; (c) Top view of the OH adsorbate and the first atomic layer of BaTiO₃.

that if the BaTiO₃ nanowire is positively polarized, the hydroxyl oxygen *2p* orbital possesses more electrons and OH is overall negatively charged. This is a robust evidence demonstrating that surface adsorbates stabilize the polarization by holding screening charges, which has an effect similar to an electrode. The leakage of charge mainly from the *2p* orbital of oxygen then results in the decay of polarization.

III. FORMALISM OF LEAKAGE CURRENT CALCULATION

There have been previous reports calculating the magnitude of leakage through ferroelectric films with tunneling models, Schottky emission, and the modified Schottky equation [35–37]. However, all these models come across difficulties in explaining all three depolarization

rate trends mentioned in Section I. B. A tunneling model alone cannot explain that for thick nanowires, decay rates are nearly thickness independent and for any thickness, the decay rates are strongly temperature dependent. On the other hand, a Schottky emission model cannot account for the thin nanowire thickness dependent rates. Here, we build a comprehensive model from the “effective velocity” point of view, which both accounts for the experimental results and illustrates their physical mechanisms.

The general expression for the time (t) dependent leakage current J can be written as

$$-\frac{\partial Q(t)}{\partial t} = J(t) = \int Q(t) n(\mathbf{k}) v_{\text{eff}}(\mathbf{k}) d^3\mathbf{k} \quad (2)$$

where $n(\mathbf{k})$ is the probability that an electron possesses a wave vector between \mathbf{k} and $\mathbf{k} + d\mathbf{k}$. $v_{\text{eff}}(\mathbf{k})$ is the effective velocity along the z direction, which is normal to the surface of the BaTiO₃ nanowire, for the electrons with wave vector \mathbf{k} . Q is the amount of extra charge (compared with neutral OH) stored in the adsorbate. In the following subsections, we define the parameterization of equation (2).

A. Wave vector distribution of electrons in adsorbate

Unlike in traditional metal electrodes, electrons occupying orbitals localized on the OH adsorbates cannot be treated as a free electron gas, and the wave vector distribution does not follow Fermi-Dirac statistics. Instead, the wave vector spectrum can be estimated from Bessel-Fourier transformation of the $2p$ orbital of oxygen, since screening charge is mainly associated with this atomic orbital. Here, the radial part of the $2p$ orbital of the oxygen is represented by a double-zeta function [38].

$$\begin{aligned} \phi_{2p}(\mathbf{r}) &= R(r) Y_{10}(\theta_r, \phi_r) \\ &= \left(c_1 \sqrt{\frac{(2z_1)^5}{4!}} r e^{-z_1 r} + c_2 \sqrt{\frac{(2z_2)^5}{4!}} r e^{-z_2 r} \right) Y_{10}(\theta_r, \phi_r) \\ &= (c'_1 r e^{-z_1 r} + c'_2 r e^{-z_2 r}) Y_{10}(\theta_r, \phi_r) \end{aligned} \quad (3)$$

$$\begin{aligned} \phi_{2p}(\mathbf{k}) &= \frac{1}{(2\pi)^{3/2}} \int e^{-i\mathbf{k} \cdot \mathbf{r}} \phi_{2p}(\mathbf{r}) d^3\mathbf{r} \\ &= -\sqrt{\frac{8}{\pi}} 4i Y_{10}(\theta_k, \phi_k) \left[\frac{c'_1 z_1 k}{(z_1^2 + k^2)^3} + \frac{c'_2 z_2 k}{(z_2^2 + k^2)^3} \right] \end{aligned} \quad (4)$$

$$n(\mathbf{k}) = |\phi_{2p}(\mathbf{k})|^2 = \frac{128}{\pi} |Y_{10}(\theta_k, \phi_k)|^2 \left[\frac{c'_1 z_1 k}{(z_1^2 + k^2)^3} + \frac{c'_2 z_2 k}{(z_2^2 + k^2)^3} \right]^2 \quad (5)$$

where Y_{10} is the spherical harmonic for $l = 1$ and $m = 0$. $c_{1,2}$ and $z_{1,2}$ are the parameters in the double-zeta function, acquired from previous reference [38]. c'_1 and c'_2 are reduced coefficients taking the normalization factors $\sqrt{\frac{(2z_1)^5}{4!}}$ and $\sqrt{\frac{(2z_2)^5}{4!}}$ into consideration. $\theta_{r,k}$ and $\phi_{r,k}$ are the angles between the directions of \mathbf{r} , \mathbf{k} and the axes in spherical coordinates. $\phi_{2p}(\mathbf{r})$ and $\phi_{2p}(\mathbf{k})$ are expressions for the oxygen $2p$ wavefunction in coordinate and wave vector representations. In this way, we obtain an analytical expression for $n(\mathbf{k})$. Here, we should note that in part II, we used pseudo wavefunctions in the DFT calculations; compared with all-electron wavefunctions, pseudo wavefunctions have lower high- k components on purpose to limit the number of plane waves used [39]. This does not affect the accuracy of charge leakage rate calculation. This is because the DFT calculation is used only to illustrate the role of screening charge and the mechanism of the depolarization process. The wave-vector distribution in this model is derived from the double-zeta function as described above. Additionally, in the later discussion, we will also include the fact that high-speed electrons lose their initial momentum quickly and drift under the effect of the electric field. Therefore, an underestimation of the high- k components has little effect on the charge dissipation speed.

B. Effective velocity

Here, we present an effective velocity model of the charge dissipation. The band diagram of the OH/BaTiO₃/Au substrate system is shown in FIG.3 (a).

We only consider the effective velocities of the electrons with the wave vector pointing toward the nanowire $\mathbf{k} \cdot \hat{\mathbf{z}} > 0$. Otherwise, the electron does not contribute to the leakage current J and its effective velocity $v_{\text{eff}} = 0$. For the electron moving toward the nanowire, the expression for effective velocity varies depending on whether the energy of the electron is higher than that of BaTiO₃ conduction band edge. The potential energy of an electron affiliated with the hydroxyl molecule oxygen $2p$ orbital is set as V_0 . The total energy for this electron can be written as the sum of its kinetic energy $T(\mathbf{k})$ and V_0 :

$$E(\mathbf{k}) = T(\mathbf{k}) + V_0 = \frac{\hbar^2 |\mathbf{k}|^2}{2m_0} + V_0. \quad (6)$$

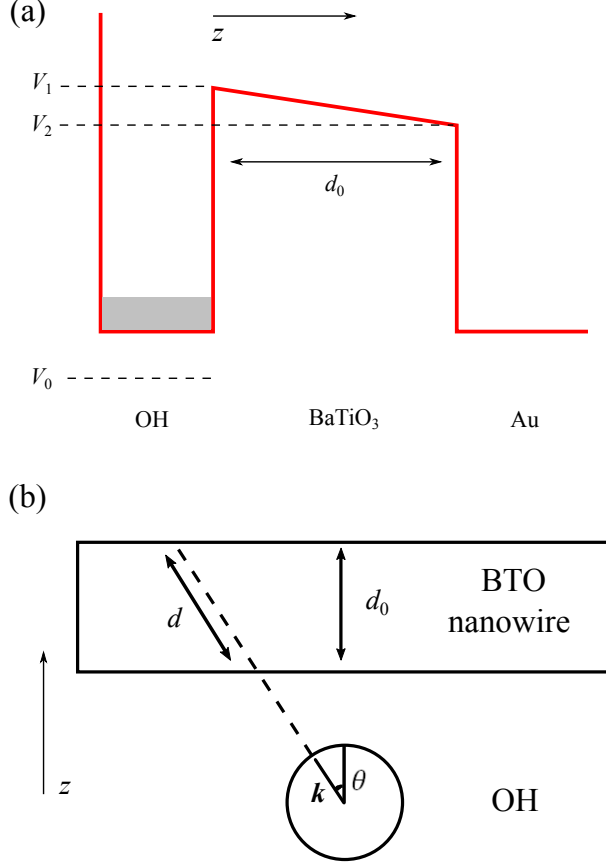

FIG. 3. (a) Band diagram of the Au electrode/oxide insulator/adsorbate electrode system; (b) Relationship of barrier thickness and direction of wave vector.

As shown in FIG. 3 (a), the conduction band for the BaTiO₃ nanowire is not flat, and the slope equals the electronic charge e times the electric field E_{fe} inside the ferroelectric nanowire. Therefore,

$$V_2 = V_1 - eE_{\text{fe}}d_0, \quad (7)$$

For the case $E(\mathbf{k}) < V_2$, the mechanism that governs the electron movement is quantum tunneling. The electron tunnels from the surface adsorbate hydroxyl to the gold electrode at the other side, through the BaTiO₃ nanowire as an energy barrier. Around T_C , the dielectric constant of BaTiO₃ is large and E_{fe} is small. Therefore, the conduction band is nearly flat and we use the approximation that the energy barrier is a cuboid with the height V_2 . The transmission coefficient $P(\mathbf{k})$, which is also the probability of one electron with wave vector

195 \mathbf{k} penetrating the barrier, could be expressed [40]:

$$P(\mathbf{k}) = \frac{4}{4 + \frac{[m_0 E + m^* (V_2 - E)]^2}{m_0 m^* E (V_2 - E)} \sinh^2 \left[\frac{2m^* d^2 (V_2 - E)}{\hbar^2} \right]^{1/2}} \quad (8)$$

196 where d is the length of the barrier. m^* is the effective mass of electrons in BaTiO₃. Assuming
 197 that the angle between the incident direction of the electron and the normal direction of the
 198 BaTiO₃ nanowire is θ , as shown in FIG. 3 (b), d could be expressed as

$$d = \frac{d_0}{\cos \theta}. \quad (9)$$

199 In this tunneling process, an electron with an initial velocity $v = \frac{\hbar \mathbf{k}}{m_0}$ has a probability
 200 $P(\mathbf{k})$ of passing the energy barrier with the thickness d . Thus, the effective velocity could
 201 be expressed as

$$v_{\text{eff}}(\mathbf{k}) = v P(\mathbf{k}) = \frac{\hbar \mathbf{k} \cdot \hat{\mathbf{z}}}{m_0} P(\mathbf{k}) = \frac{\hbar k \cos \theta}{m_0} P(\mathbf{k}). \quad (10)$$

202 When the hydroxyl electron energy is higher than that of the BaTiO₃ conduction band
 203 edge $E(\mathbf{k}) > V_1$, the electron is not classically forbidden to enter the BaTiO₃ nanowire.
 204 However, very high velocity electrons could have very short mean free paths. Moreover, in
 205 the BaTiO₃ crystal, which is an insulator and possesses a small mean free path [41], the
 206 electron loses its initial momentum quickly and drifts under the effect of electric field E_{fe}
 207 inside the ferroelectric nanowire:

$$v_{\text{eff}} = \mu E_{\text{fe}}, \quad (11)$$

208 where μ is the electronic mobility, which depends on temperature, intermediate energy levels
 209 and lattice vibrations. Lattice vibrations have a significant influence on the drift mobility
 210 due to electron-phonon interactions [42–45], in which an electron may lose or gain energy in
 211 a collision. This effect will be discussed in the following subsection.

212 For the final case, $V_2 < E(\mathbf{k}) < V_1$, the electron first tunnels through an energy barrier
 213 and then drifts in the conduction band. The effective velocity is given by

$$v_{\text{eff}} = \mu E_{\text{fe}} P(\mathbf{k}). \quad (12)$$

214 For this case, the energy barrier goes to zero within the nanowire. At this condition, the
 215 Wentzel–Kramers–Brillouin (WKB) [46] approximation fails. Since $E(\mathbf{k})$ is close to V_1 , we
 216 approximate $P(\mathbf{k})$ to 1.

Even though the approximations in the first and last cases overestimate the tunneling current, later we will point out that despite this, the tunneling current is still a negligible contribution to the overall current.

C. Electric Properties of BaTiO₃ Nanowire

The relationship of surface charge density Q , electric displacement D_{fe} and electric field E_{fe} though the insulator is given by dielectric constant $\epsilon(T)$ [11]:

$$Q(t) = D_{\text{fe}} = \epsilon(T) \epsilon_0 E_{\text{fe}}. \quad (13)$$

According to the Lyddane-Sachs-Teller [47] relation, the temperature dependent static dielectric constant is expressed as:

$$\frac{\epsilon(T)}{\epsilon_\infty} = \frac{\prod_i \omega_{L_i}^2(T)}{\prod_i \omega_{T_i}^2(T)} \quad (14)$$

where ω is the frequency of lattice vibration and T_i and L_i represent transverse and longitudinal modes. Approaching T_C , a transverse optical mode ω_{TO} becomes “soft”, indicating the occurrence of phase transition [48–50]:

$$\omega_{\text{TO}}^2 \approx A(T - T_C) \quad (15)$$

228

$$\epsilon(T)^{-1} \propto \omega_{\text{TO}}^2 = A'(T - T_C) \quad (16)$$

where A and A' are constants, and for BaTiO₃ bulk [51, 52], $T_C \approx 393$ K. However, for a thin film or nanowire, if polarization exists, a depolarization field is induced due to the incomplete charge compensation of polarization charge [13, 53, 54]. The depolarization field, which is anti-parallel to polarization, becomes significant as the thickness decreases. It also applies an electric force on the ions, and as a consequence, the soft vibrational mode is hardened. With the depolarization field effect included, the temperature dependent soft mode frequency for thin films should be rewritten as

$$\omega_{\text{TO}}^2 \approx A(T - T'_C) \quad (17)$$

236

$$\epsilon(T)^{-1} = A'(T - T'_C) \quad (18)$$

237 and

$$T'_C < T_C. \quad (19)$$

238 The depolarization field effect hardens the soft mode, increases the vibrational frequency,
 239 suppresses the ferroelectricity and lowers the T_C . The values of T'_C for different thicknesses
 240 could be inferred from T_C , which were previously experimentally measured [4].

241 Previous studies illustrated that the electronic mobility in BaTiO₃ varies over a large
 242 range (10^{-3} – 10^{-1} cm²/V–s) [45, 55, 56]. The variation of mobility could be attributed to
 243 the different trap levels, types and concentrations from the fabrication process. Despite
 244 the uncertainty, there is a general rule that electron mobility is determined by the optical
 245 phonons [42–45].

246 Many studies in recent years pointed out that scattering by the soft transverse optical
 247 mode is the primary factor affecting electron drift [45, 57, 58]. In this case [58]:

$$\mu = \frac{f(T)}{\epsilon(T)} \propto f(T) \omega_{\text{TO}}^2 \quad (20)$$

248 and $f(T)$ depends weakly on T for BaTiO₃ [57, 58]. For $T > T'_C$

$$\mu \approx B \omega_{\text{TO}}^2 = B' (T - T'_C) \quad (21)$$

249 where B and B' are constants. An explicit explanation about the soft mode dependent
 250 mobility was proposed in Ref. [45]. In brief, according to thermodynamics, the mean squared
 251 polarization fluctuation δP is related to the dielectric constant as [59].

$$\langle \delta P^2 \rangle = k_B T \epsilon / V \propto 1 / \omega_{\text{TO}}^2 \quad (22)$$

252 where k_B is Boltzmann constant and V is the volume. For the case $T > T'_C$, a high soft
 253 mode frequency means a small dielectric constant, large mean-square TO phonon amplitude
 254 and polarization fluctuation. Besides, in a small region with an approximately uniform
 255 polarization fluctuations, shifts in the conduction band edge $\Delta \mathcal{E}_c$ is [60]

$$\Delta \mathcal{E}_c = \text{const} + \beta \delta P^2 \quad (23)$$

256 where β is the polarization–potential parameter, which has a typical value $\beta \approx 2 \text{ eV m}^4/\text{C}^2$.
 257 In the nanowire, the low soft mode frequency leads to inhomogeneity in $\Delta \mathcal{E}_c$, which then
 258 results to locally different effective masses and electronic energies. Therefore, an electron
 259 traveling through the wire scatters more. This is similar to an electron traveling on a curved
 260 path and harder to accelerate. A lower soft mode frequency means more scattering, a shorter
 261 relaxation time, τ_e , and a smaller electron mobility, since electron mobility is given by [61]

$$\mu = \frac{e \tau_e}{m^*} \quad (24)$$

Thus, in this simulation, we use the empirical expression of electron mobility as shown in equation (21).

IV. RESULTS AND DISCUSSIONS

With the expressions of effective velocity deduced in different wave vector range,

$$v_{\text{eff}}(\mathbf{k}) = \begin{cases} \frac{\hbar \mathbf{k}}{m} \cdot P(\mathbf{k}) & \text{if } E(\mathbf{k}) < V_2, \mathbf{k} \cdot \hat{\mathbf{z}} > 0 \\ \mu E_{\text{fe}} P(\mathbf{k}) & \text{if } V_2 < E(\mathbf{k}) < V_1, \mathbf{k} \cdot \hat{\mathbf{z}} > 0 \\ \mu E_{\text{fe}} & \text{if } E(\mathbf{k}) > V_1, \mathbf{k} \cdot \hat{\mathbf{z}} > 0 \\ 0 & \text{if } \mathbf{k} \cdot \hat{\mathbf{z}} < 0, \end{cases} \quad (25)$$

we could calculate the time evolution of surface charge with equation (2).

The expression of current density was shown in equation (1). In the calculation of charge density evolution with time, the initial charge density used in the simulation is $Q(0) = 0.26 \text{ C/m}^2$ [32], which is the spontaneous polarization for the tetragonal phase of BaTiO_3 . The time window is selected as 10^4 s , which is long enough to demonstrate the general trend of time evolution of surface charge in adsorbate OH. Other parameters involved in the presented tunneling and modified Schottky model are listed in TABLE II. Most of the parameters are from previous references. The difference of the potential energy of electrons in the adsorbate oxygen $2p$ orbital (V_0) and in the conduction band formed by titanium $3d$ orbitals (V_1) is estimated from the band gap of BaTiO_3 (3.20 eV) [62]. This is a good approximation because the adsorbate oxygen $2p$ orbital is approximately at the same level with the valence band formed by oxygen $2p$ orbitals of the nanowire.

$$V_1 - \overline{E(\mathbf{k})} \approx 3.20 \text{ eV} \quad (26)$$

where $\overline{E(\mathbf{k})}$ is the average energy of electrons in the adsorbate oxygen $2p$ orbital, and

$$\overline{E(\mathbf{k})} = \overline{T(\mathbf{k})} + V_0 \quad (27)$$

$$\overline{T(\mathbf{k})} = \int_0^\infty n(\mathbf{k}) \frac{\hbar^2 \mathbf{k}^2}{2m_0} d^3 \mathbf{k} = 68.28 \text{ eV} \quad (28)$$

$$V_1 - V_0 = V_1 - \overline{E(\mathbf{k})} + \overline{T(\mathbf{k})} = 71.48 \text{ eV.} \quad (29)$$

281 In the modeling, the surface charge density Q decays with time t , but not exactly expo-
 282 nentially. We fit each Q *vs.* t curve with an exponential function by the least squares fitting
 283 method. In this way, we obtain decay constants from this model that can be compared with
 284 experimental ones. B' of equation (21) is the only parameter calculated by fitting the data
 285 in experiments to the decay rates calculated by this analytical model, rather than from any
 286 references or *ab initio* calculation.

287 TABLE II. Parameters involved in the presented tunneling and modified Schottky model of
 288 nanowire depolarization.

Parameter	Description	Value
T'_C (5 nm)	T_C for 5 nm nanowire ^a	340.3 K
T'_C (7 nm)	T_C for 7 nm nanowire ^a	355.2 K
T'_C (9 nm)	T_C for 9 nm nanowire ^a	367.9 K
T_C	T_C for thick nanowires ^a	391 K
c_1	Parameter in equation (3) ^b	0.72540
289 c_2	Parameter in equation (3) ^b	0.35173

293 ^d From the band gap estimation

294 ^e Estimated from reference [52]

295 ^f The unit is cm²/VsK

The decay rates calculated from this model and experimental data are shown in FIG. 1. Experimental data are marked with red circles and theoretically calculated ones are blue squares. Symbols for decay rates of a given thickness are connected with dashed lines, to demonstrate their temperature dependence. From the comparison, it could be seen that this model not only simulates the experimental results to a good extent, but also sheds light on the general rules of ferroelectric leakage current.

For nanowires with any thicknesses, calculations based on equations (2) and (25) demonstrate that tunneling current provides a negligible part of the total leakage current. Even for the thinnest nanowires (5 nm) with a surface charge density $Q(0) = 0.26 \text{ C/m}^2$, the tunneling current is around 10^{-6} A/m^2 or less, generally no more than 1 percent of the total leakage current. Emission of electrons with energies higher than the barrier contributes nearly all the current. The fact that tunneling, whose rate is thickness dependent, plays a minor role is consistent with the experimental finding that decay rates are thickness independent for thick nanowires [63].

For thin nanowires, at a certain temperature which is above T_C , the soft mode frequency decreases with thickness due to the depolarization field effect. A thinner nanowire corresponds to a higher soft mode frequency and a smaller dielectric constant, as shown in equation (17). Thus, the electric field through a thinner nanowire is larger and accelerates the electron emission. Meanwhile, a higher transverse optical mode frequency results in a faster electron drift mobility. This makes the leakage current and polarization decay constant significantly thickness-dependent for thin wires. For thick nanowires, the soft mode frequency at a certain temperature approaches that of the bulk BaTiO_3 crystal. In this range, thickness affects the electric field, electron mobility, and leakage current little. It is worth mentioning that the conclusion, that leakage current depends on thicknesses only for thin nanowires or films, is consistent with previous studies [63–65].

In this study, the surface adsorbate OH plays the role of top electrode, which is the source of nonequilibrium charge carriers. This modified Schottky model, simulating leakage current in ferroelectric oxides, differs from the traditional Schottky emission model in many aspects. The electrons are localized in a $2p$ orbital, and their wave vector distribution is now not based on Fermi-Dirac statistics. Different from the traditional Schottky emission model, in which the thermal population of electrons leads to the temperature dependence of leakage current, temperature dependent leakage current is attributed to change of electric

field through the nanowire and electronic mobility accompanied with the hardening (or softening) of the transverse optical mode in this model.

V. CONCLUSION

In summary, the depolarization process of BaTiO₃ nanowires has been studied by both experiment and first principles calculation. We investigated the mechanisms which govern the polarization decay and drew several principles. A new proposed theoretical model, which combines molecular orbital theory, quantum tunneling and the modified Schottky equation, could explain successfully the general trends in the temperature and nanowire thickness dependent decay rates. Our study demonstrates that the surface adsorbate plays a significant role in stabilizing ferroelectricity and that depolarization is a process of charge leaking from the hydroxyl surface adsorbate to the gold substrate.

&= -\sqrt{\frac{8}{\pi}} 4i Y_{10}(\theta_k, \phi_k) \left[\frac{c'_1 z_1 k}{(z_1^2 + k^2)^3} + \frac{c'_2 z_2 k}{(z_2^2 + k^2)^3} \right]
\end{aligned}$$

Appendix B: Derivation of equation (8)

The derivation follows the idea in Ref. [40]. We consider that case that an electron with the wave vector k penetrates a BaTiO₃ (BTO) nanowire.

FIG. 4. Energy barrier diagram.

As shown in FIG. 4, The length of the penetration path is d . The energy of the electron is $E(\mathbf{k})$ and the energy of the BaTiO₃ conduction band is V_2 . In the region of OH, the wave function is the plane wave including incident part and reflection part

$$\varphi_1(x) = Ae^{ikx} + Be^{-ikx} \quad (x < 0) \quad (\text{B1})$$

$$k = \left(\frac{2m_0 E}{\hbar^2} \right)^{1/2} \quad (\text{B2})$$

In the BaTiO₃ region, the Schrödinger equation is

$$-\frac{\hbar^2}{2m_0} \frac{d^2 \varphi(x)}{dx^2} + V(x) = E_{BTO} \varphi(x) \quad (\text{B3})$$

When we consider the electrons around the conduction band, we can write the potential energy term into effective mass

$$-\frac{\hbar^2}{2m^*} \frac{d^2 \varphi(x)}{dx^2} = E_{BTO} \varphi(x) \quad (\text{B4})$$

$$E_{BTO} = V_2 - E(\mathbf{k}) \quad (\text{B5})$$

where m^* is the effective mass. The solution of the above Schrödinger equation is

$$\varphi_2(x) = Ce^{k'x} + De^{-k'x} \quad (0 < x < d) \quad (\text{B6})$$

461

$$k' = \left(\frac{2m^*(V_2 - E)}{\hbar^2} \right)^{1/2} \quad (\text{B7})$$

462 With the analysis above, wave function in each region is summarized as

$$\begin{cases} \varphi_1(x) = Ae^{ikx} + Be^{-ikx} & x < 0 \\ \varphi_2(x) = Ce^{k'x} + De^{-k'x} & 0 < x < d \\ \varphi_3(x) = Fe^{ikx} & x > d \end{cases} \quad (\text{B8})$$

463 The tunneling probability is given by

$$P = \frac{|F|^2}{|A|^2} \quad (\text{B9})$$

464 $\varphi(x)$ and $d\varphi(x)/dx$ must be continuous at the boundaries.

$$A + B = C + D \quad (\text{B10})$$

465

$$ik(A - B) = k'(C - D) \quad (\text{B11})$$

466

$$Ce^{k'd} + De^{-k'd} = Fe^{ikd} \quad (\text{B12})$$

467

$$k'Ce^{k'd} - k'De^{-k'd} = ikFe^{ikd} \quad (\text{B13})$$

468 From equation (B12) and (B13) we have,

$$C = \frac{(k' + ik) Fe^{ikd}}{2k' e^{k'd}} \quad (\text{B14})$$

469

$$D = \frac{(k' - ik) Fe^{ikd}}{2k' e^{-k'd}} \quad (\text{B15})$$

470 From (B10) $\times ik$ + (B11), we have

$$A = \frac{(ik + k') C + (ik - k') D}{2ik} \quad (\text{B16})$$

471 Substitute (B14) and (B15) into (B16) gives

$$A = \frac{Fe^{ikd}}{4ikk'} \left[(ik + k')^2 e^{-k'd} - (ik - k')^2 e^{k'd} \right] \quad (\text{B17})$$

472

$$\frac{F}{A} = \frac{4ikk' e^{-ikd}}{2(k^2 - k'^2) \sinh k'd + 4ikk' \cosh k'd} \quad (\text{B18})$$

$$P = \frac{|F|^2}{|A|^2} = \frac{16k^2k'^2}{4(k'^2 - k^2)^2 \sinh^2 k'd + 16k^2k'^2 \cosh^2 k'd} \quad (\text{B19})$$

474 Since $\cosh^2 k'd = 1 + \sinh^2 k'd$,

$$\begin{aligned} P &= \frac{16k^2k'^2}{4(k'^2k^2)^2 \sinh^2 k'd + 16k^2k'^2} \\ &= \frac{4}{4 + \frac{(k^2 + k'^2)^2}{k^2k'^2} \sinh^2 k'd} \end{aligned} \quad (\text{B20})$$

475 Therefore,

$$P = \frac{4}{4 + \frac{[m_0E + m^*(V_2 - E)]^2}{m_0m^*E(V_2 - E)} \sinh^2 \left[\frac{2m^*d^2(V_2 - E)}{\hbar^2} \right]^{1/2}} \quad (\text{B21})$$
