(Dated: May 4, 2015)

Topological Majorana fermion (MF) quasiparticles have been recently suggested to exist in semiconductor quantum wires with proximity induced superconductivity and a Zeeman field. Although the experimentally observed zero bias tunneling peak and a fractional ac-Josephson effect can be taken as necessary signatures of MFs, neither of them constitutes a sufficient “smoking gun” experiment. Since one pair of Majorana fermions share a single conventional fermionic degree of freedom, MFs are in a sense fractionalized excitations. Based on this fractionalization we propose a tunneling experiment that furnishes a nearly unique signature of end state MFs in semiconductor quantum wires. In particular, we show that a “teleportation”-like experiment is not enough to distinguish MFs from pairs of MFs, which are equivalent to conventional zero energy states, but our proposed tunneling experiment, in principle, can make this distinction.

\textbf{Introduction:} Majorana fermions \cite{1} (MF) are localized particle-like neutral zero energy states that occur at topological defects and boundaries in superconductors. A MF creation operator is a hermitian second quantized operator $\gamma^\dagger = \gamma$ which anti-commutes with other fermion operators. The hermiticity of MF operators implies that they can be construed as particles which are their own anti-particles \cite{1–4}. The key issues at this time in the condensed matter context are two fold, first, we must predict and characterize materials supporting MFs and second, we must detect them experimentally. In this paper we address the second issue of experimental detection by proposing a nearly sufficient experimental signature for MFs.

MFs have recently been proposed to exist in the topologically superconducting (TS) phase of a spin-orbit (SO) coupled cold atomic gases \cite{5}, semiconductor 2D thin film \cite{6, 7} or 1D nanowire \cite{7–9} with proximity induced s-wave superconductivity and Zeeman splitting from a sufficiently large magnetic field. In principle, the MFs in such systems may be detected either by measuring the zero-bias conductance peak (ZBCP) from tunneling electrons into the end MFs \cite{7, 10–13}, by detecting the predicted fractional ac Josephson effect \cite{8, 9, 14–20}. The semiconductor Majorana wire structure, which will be the system of our focus, is of particular present interest since there is experimental evidence for both the ZBCP \cite{21–24} and the fractional ac Josephson effect in the form of doubled Shapiro steps \cite{21}.

Despite their conceptual simplicity, neither the ZBCP nor the fractional ac-Josephson effect experiments constitute a sufficient proof of MFs at the ends of topological superconducting wires. A non-quantized $(2e^2/h)$ zero bias peak, such as that observed in the recent experiments \cite{22–24}, can in principle arise even without end state MFs \cite{25–27}. Similarly, a fractional ac-Josephson effect can exist even in Josephson junctions made of ordinary quasi-1D $p$-wave superconductors such as organic superconductors \cite{15} or the non-topological phase of the semiconductor nanowire \cite{28}. Given these caveats as well as the considerable complexity of existing experiments, there have been several alternative proposals to detect the presence of MFs \cite{29–32}. Based on the inherent quantum non-locality of MFs, in this work we propose an alternative tunneling experiment on semiconductor Majorana wires that furnishes a nearly sufficient signature of end-state MFs. We discuss in detail why only topological systems would show such quantum non-locality, which would even be absent for systems with conventional Andreev states at each end.

\textbf{Non-local electron transfer} Non-locality arises in MFs because they differ from conventional complex (Dirac) fermions in that they have no occupation number associated with them. To define a quantum state of a system with MFs we must consider a pair of MFs. The pair of MFs $\gamma_a$ and $\gamma_b$ at the ends $a$ and $b$ of a nanowire (NW) shown in Fig. 1 can be combined into a zero-energy complex fermion operator $d^\dagger = \frac{1}{2}(\gamma_a + i\gamma_b)$ associated with the pair of MFs $\gamma_a$ and $\gamma_b$ \cite{14}. The quantum state of the system is then determined by the eigenvalue of $n_d = d^\dagger d = 0, 1$. Since the fermion parity $F_P = (-1)^n_d$ associated with the operator $d^\dagger$ is related to the MFs by

$$F_P = (-1)^n_d = i\gamma_a\gamma_b,$$

we see that the fermion parity of the whole system is determined by non-local correlations between the fractionalized MFs $\gamma_a$ and $\gamma_b$. In fact, the fractionalization of the $F_P$ into a pair of spatially separated operators $\gamma_{a,b}$ in one-dimensional systems with localized fermion excitations, is a unique characterization of the topological
state of the system [33]. Our central concern is how to probe this non-locality to provide a robust and sufficient criterion of MFs.

An immediate idea involves trying to inject an electron into $\gamma_a$ and retrieve it from $\gamma_b$ [34–37]. By connecting leads to the left and the right ends of the TS wire in Fig. 1, one could imagine that an electron injected into the end $a$ flips the occupation number $n_a$ from $n_a = 0$ to $n_a = 1$. The injected electron can then escape from the end $b$ flipping the state back from $n_b = 1$ to $n_b = 0$. Such a process where an electron can enter from one end $a$ and exit at the other lead $b$, can be interpreted as a transfer of an electron, which we will refer to as Majorana-assisted electron tunneling. However, as has been discussed in previous works [34, 35], such a transfer occurs in a way so as to not violate locality and causality.

The amplitude for the Majorana-assisted electron tunneling [35, 36] can be written in terms of the retarded Green function as

$$G_{mn}^R(\tau) = -i \langle [c_n^\dagger(\tau), c_m(0)] \rangle \Theta(\tau),$$

(2)

where $\tau$ is the time-interval between the tunneling events, $\Theta(\tau)$ is the Heaviside step function and $c_m^\dagger$ are the electron operators at the left (i.e. $m = a$) and right (i.e. $m = b$) end of the wire. In the low-energy limit in the topological state, the electron-operators at the ends $c_{a,b}^\dagger$ can be approximated by the end Majorana modes $\gamma_{a,b}$. Thus, the amplitude $G_{ab}^R(\tau)$ represents Majorana-assisted non-local electron tunneling between the ends $a$ exits as a hole at the end $b$ and has a non-zero value in the topological phase given by

$$G_{ab}^R(\tau) = -i F_P, \quad (3)$$

where $F_P \equiv i (\gamma_a(0) \gamma_b(0))$ is the fermion parity of the TS system. Since $G_{ab}^R(\tau)$ is directly related to the fermion parity $F_P$, the detection of such a non-vanishing amplitude for a non-local Green function $G_{ab}^R(\tau)$ is a signature of the fractionalization associated with MFs.

Charging energy: In equilibrium, the degeneracy of the different fermion parity states characteristic of a TS system lead to fluctuations in $F_P$, that would result in a vanishing average for the tunneling amplitude $G(\tau; ab)$. This is remedied [37] by introducing a charging energy $E_C$ on the superconducting island supporting the NW, which makes one of the fermion parities energetically favorable over the other. To compute $G_R$, we consider the Hamiltonian for the NW in Fig. 1 as

$$H = H_{BCS} + 4E_C(\delta \hat{n}_W/2 - \gamma_g^2) - E_J \cos(\phi), \quad (4)$$

where $E_C$ is the charging energy of the wire, $H_{BCS}$ is the BCS Hamiltonian for the proximitized NW, $\hat{n}_W$ is the number of electrons in the NW. Here $\hat{N}$ is the total number of Cooper pairs with the SC island, the NW and the gate and is a variable that is conjugate to the phase $\phi$, $n_g$ is the gate charge. To control the charging energy of the NW we couple it to a superconductor with Josephson strength $E_J$, which can in principle be controlled using a SQUID geometry [44].

While coupling to the superconducting lead in Fig. 1 breaks charge conservation, it preserves fermion parity $F_P$, which is related to the number of electrons modulo two [45]. In the limit that $E_J \gg E_C$, so that the only effect of charging energy is an energy splitting $\delta = 16 (E_C / 2 \pi^2)^{1/4} e^{-\sqrt{8E_J/E_C}} \cos 2\pi n_g$ between the different fermion parity states $F_P = \pm 1$. Thus the effective Hamiltonian is written as $H_{eff} = H_{BCS} + F_P \delta$. Since $F_P$ and $H_{BCS}$ commute, expanding $H$ in terms of $H_{BCS}$ the Green function $G_R(\tau)$ can be written as

$$G_{mn}^R(\tau) = -i \langle \Theta(\tau) \langle [c_m^\dagger(\tau), c_n(0)] \rangle e^{-i F_P \delta} / e^{-i F_P \delta} \rangle_0, \quad (5)$$

where $\langle \ldots \rangle_0$ is the thermal expectation with respect to $H_{BCS}$.

Coincidence probability: The amplitude $G_{ab}^R(\tau)$ can lead to a so-called coincidence probability $P_c(\tau)$, which maybe measured by using a joint measurement by two point contact detectors at the two ends [35, 41]. Alternatively, the non-local transfer of electron can also be measured by a non-local conductance or transconductance.
between the ends a and b in Fig. 1. This measurement does not require closing the loop (L) in Fig. 1 and would require adding a lead to the end a. In such a set-up, a voltage $V_a$ applied to the left-lead a (relative to the SC) results in a current $I_b$ in the right lead b. Using results of Ref. 34 for symmetric $t_a = t_b = t$ we find that

$$\frac{dI_b}{dV_a} = \frac{32V_a}{16\Gamma^2 + (\delta^2 - V_a^2)^2 + 8\Gamma^2(\delta^2 + V_a^2)},$$

(6)

which clearly vanishes for $\delta \to 0$ (i.e. vanishing charging energy $E_C \to 0$). Here $\Gamma \propto t^2$ is the lead-induced broadening of the MFs.

**Topological versus non-topological systems:** However, a coincidence measurement does not directly imply a non-zero $G^R(\tau; ab)$ in more general situations. The amplitude $G^R_{ab}(\tau)$ in Eq. 2, reflects the amplitude for being able to transfer an electron from a to b while leaving the state $|g\rangle$ invariant. On the other hand, the measurement of the coincidence probability, $P_c$, does not keep track of the internal state of the system. For a general system (i.e. one that may be topological or non-topological), $P_c$ for an electron entering at $a$ and exiting at $b$ can be written more generally as

$$P_c(\tau) = \sum_{g_1,g_2} \langle g_2|c_b(0) c^\dagger_a(\tau)|g_1\rangle^2,$$

(7)

where $g_1, g_2$ are the internal states of the wire, which are not necessarily identical. While TS systems with MFs have a non-degenerate ground state in a given fermion parity sector, more general systems with zero-energy Dirac end states may have multiple allowed values for $g_1, g_2$. Therefore, the coincidence probability $P_c$ cannot be considered a unique signature for a topological system.

An important example of the inequivalence of $P_c(\tau)$ and $G^R(\tau; ab)$ is a non-topological superconductor with Andreev zero mode at each end. The quantum state is characterized by the occupancy $n_a, n_b$ of the two conventional zero energy end modes. We can easily have $P_c \neq 0$ in this non-topological setup. Suppose the initial state is $g_1 \equiv (n_a = n_b = 0)$, then the sum for $P_c$ in Eq. 7 would have a non-zero contribution from $g_2 \equiv (n_a = n_b = 1)$. The tunneling of an electron from the lead into the zero-mode at $a$ changes the occupation from $n_a = 0$ to $n_a = 1$. On the other hand, the electron required to change the occupation of the state $b$ from $n_b = 0$ to $n_b = 1$ comes from breaking of a Cooper pair. The other electron from the broken Cooper pair is emitted into the lead in the vicinity near $b$. Note that the process conserves the number of electrons within the system and cannot be eliminated even by the introduction of a finite charging energy [37]. Therefore in order to clearly distinguish this case from the process of Majorana-assisted electron tunneling (that also returns a non-zero $P_c$), we require $G^R(\tau; ab)$ given in Eq. 2 itself to be non-zero. In other words, we require that the system return to the same state $g$ after the tunneling process, so the same electron that enters at $a$ leaves at $b$. The Green function between the ends of a non-topological systems, $G^R_{ab}(\tau)$, vanishes. This is because introducing a superconducting phase-slip through a non-topological system which transforms $c_b \to -c_b$ and flips the sign of the Green function without affecting the Hamiltonian. In fact, in the Supplementary material [38] we explicitly show how this vanishes even in the case of decoupled pairs of MFs.

**Proposed set-up:** The Majorana-assisted electron transfer $G^R_{ab}(\tau)$ can be measured by the setup in Fig. 1 consisting of an external semiconducting loop (L) that is connected to the ends $a$ and $b$ of the NW. The Green function $G^R(\tau)$ can be determined by measuring the Andreev conductance from the semiconducting loop $L$ into the superconductor shown in Fig. 1 in the tunneling regime (i.e. small tunneling) with tunneling amplitude $t_{ab}$ between the ends of the NW and loop. The tunneling Hamiltonian between $L$ and NW is written as

$$H_t = [t_a c^\dagger_a c_{L,a} + t_b c^\dagger_b c_{L,b}] + h.c.,$$

(8)

where $c_{L,a}, c_{L,b}$ are fermion annihilation operators in the loop $L$ near the ends $a,b$ and the flux affects $t_b$ as $t_b = t_b,e^{i\varphi/2}$ where $\varphi = \frac{2\pi a}{\xi}$. The zero-bias conductance can be calculated using the Meir-Wingreen formula and expanding to lowest non-vanishing order in the tunneling amplitude as

$$\sigma(\varphi) = \int d\epsilon \text{sech}^2 \frac{\epsilon}{2T} \sum_{m,n} \text{Im}[\Gamma_{m,n}(\epsilon) G^R_{m,n}(\epsilon)],$$

(9)

where $\Gamma_{m,n}(\epsilon) = t_n \rho_{mn}(\epsilon) t^*_n$ is the imaginary part of the lead-induced self-energy and the retarded Green function in the time-domain is written as $G^R_{R,m}(t) = \Theta(t) \langle \{ c_m(t), c^\dagger_n(0) \} \rangle$. Here the indices $m, n$ are summed over the ends $a, b$ and $\rho = \text{Im}(G_{L,0}(0))$ is the density of states, which can be calculated as the imaginary part of the retarded Green function in the loop.

Ignoring the energy dependence of the lead density of states $\rho_{mn}(\epsilon)$ and choosing (for simplicity) a symmetric lead and contacts with $|t_a| = |t_b|$, the imaginary part of the lead self-energy $\Gamma$ can be written as $\Gamma_{aa} = \Gamma_{bb} = \Gamma_0$ and $\Gamma_{ab} = \lambda_0 e^{i\epsilon/2}$ for appropriately chosen constants $\Gamma_0$ and $\lambda$. Within this set of simplifying approximations, the conductance is found to be

$$\sigma(\varphi) = \int d\epsilon \text{sech}^2 \frac{\epsilon}{2T} \Gamma_0 \text{Im} \left[ G^R_{a,a}(\epsilon) + G^R_{b,b}(\epsilon) + \lambda(G^R_{a,b}(\epsilon) e^{i\epsilon/2} + e^{-i\epsilon/2} G^R_{b,a}(\epsilon)) \right].$$

(10)

It is clear from the above formula that $\sigma(\varphi)$ shows 4π-periodic oscillations whenever the non-local tunneling amplitude, $G^R_{ab} \neq 0$ across the NW is finite. This direct measurement of the non-vanishing tunneling amplitude
The magnitude of the chemical potential in the topological case, as expected from the fractional Josephson effect in TS systems \[11, 14\]. However, the 4\(\pi\)-periodicity of the current in the Josephson junction in a TS system relies on fermion parity protection, which is typically accomplished by using a non-equilibrium AC Josephson measurement \[11\]. In principle, protecting the fermion parity by a charging energy would allow the observation of the fractional Josephson effect in equilibrium. Observation of the fractional Josephson effect protected by \(E_C\) cannot occur in previously proposed linear Josephson junctions\[11, 14, 17–20\], which always have an additional pair of uncoupled MFs contributing to the fermion parity. The loop geometry in Fig. 1 would in principle allow the 4\(\pi\)-periodic current phase relationship to be measured. However, such a current phase relation, would be relatively difficult to measure since the Josephson current would have to be measured in a closed loop circuit. Finally, we note that the 4\(\pi\)-periodicity in both the non-local transport and the Josephson case does not violate the Byers-Yang theorem \[47\] because of the long ranged Coulomb charging energy \(E_C\), which is not accounted for in the BCS mean-field theory.

**Summary and Conclusion:** In this paper we have proposed a scheme for uniquely identifying the Majorana-assisted non-local electron tunneling between two MFs at the ends of a wire in the TS phase. In principle, such a non-local transfer of electrons may be observable by a coincidence measurement \[35, 36, 41\]. However, as we have shown here that the Majorana assisted electron tunneling process using either a coincidence detection \[35, 41\] or by measuring the transconductance with a charging energy \[37\], while interesting, cannot be taken as a definitive signature of MF modes because even conventional near-zero energy states trapped near the spatially separated leads can also produce such non-local signature. Instead we have proposed an interferometry experiment \[37\] appropriately generalized to geometries without edge modes. We have shown that such a measurement can distinguish conventional and Majorana zero modes. Our proposed non-local correlation experiment in terms of tunneling, which requires the inclusion of charging energy to fix the fermion parity, provides a direct verification of the non-locality of MFs in TS wires. We emphasize that the non-locality of the end state MFs arises from the non-locality
of the fermion parity, which is unique to topological systems and cannot be emulated by conventional systems [33].
