Department of Physics, Montana State University, Bozeman, Montana 59717-3840, USA

The Co$^{2+}$ ions of CoSb$_2$O$_6$ exhibit local magnetic order below $T_N = 13.45$ K. Analysis of the magnetic susceptibility above $T_N$ using an Ising model of Co-Co dimers, yields a magnetic exchange coupling $J_y/k_B = -10.603(6)$ K ($k_B$ is the Boltzmann constant). The transition at $T_N$ is accompanied by a spin gap in the heat capacity ($\Delta_2/k_B = 33.92(9)$ K). Highly anisotropic behavior of the thermal expansion is observed, and the influence of local magnetic order is evident. A critical exponent of $\alpha = 0.103(3)$ is obtained from analysis of the critical behavior of the heat capacity and thermal expansion near $T_N$, similar to the value expected for the three dimensional Ising universality class.

I. INTRODUCTION

Fermions constrained to one dimension (1D) are known to exhibit boson-like behavior of some collective excitations.\textsuperscript{1,2} This topic, referred to as Luttinger-liquid theory, is relevant beyond the purely-1D case\textsuperscript{3} and it is applicable to mobile fermions and those constrained to lattice sites.\textsuperscript{3} Luttinger-liquid behavior can be investigated in bulk solids, but purely-1D states never exist there because interchain interactions result in higher-dimensional behavior. For example, a 1D chain of magnetic moments would not exhibit long-range-magnetic order due to quantum fluctuations, but interchain coupling among a collection of chains can induce order.\textsuperscript{3} The coupling of 1D chains leads to substantial mathematical complexity,\textsuperscript{4,5} and a theoretical understanding is still developing. For example, the presence of simple perturbations, such as magnetic field, destroy the integrability.\textsuperscript{6} Thus, the study of bulk compounds with 1D chains of magnetic moments is important for developing a better understanding of 1D physics.

Transition-metal oxides with the chemical formula AB$_2$O$_6$, where A is a 3d transition metal and B is either Sb or Ta, are an interesting class of compounds with 1D magnetic chains. In most cases, they possess a trirutile structure with the A$^{2+}$ cations located at the corners and the B$^{5+}$ cations forming two parallel sheets.\textsuperscript{7} Their low-dimensional magnetic behavior is evident from experiments\textsuperscript{8–12} and electronic structure calculations.\textsuperscript{13,14} In the case of CuSb$_2$O$_6$, orbital order is believed to promote antiparallel ordering of the magnetic moments along the [110] direction at $z = 0$ and the [110] direction at $z = 1/2$, which is commonly referred to as the two-sublattice antiferromagnetic structure. Spin-exchange constants of NiTa$_2$O$_6$, obtained\textsuperscript{14} from density functional theory (DFT), exhibit a dominant antiferromagnetic exchange along the same structural diagonals as CuSb$_2$O$_6$. In contrast, MnSb$_2$O$_6$ (trigonal crystal structure) possesses a cycloidal magnetic structure, where all spin-exchange constants are of similar magnitude.\textsuperscript{15}

The fact that some of these compounds can possess one dimensional (1D) chains that are weakly coupled to one another was proven through observations of an anisotropic magnetocaloric effect (MCE)\textsuperscript{12} in NiTa$_2$O$_6$ and CoSb$_2$O$_6$. The MCE is manifested as a downward shift of the peak in heat capacity $C_P$ with application of magnetic field $H$. If $H$ is applied parallel to the 1D chains of one sublattice, it is then perpendicular to the 1D chains of the second sublattice. This magnetic field orientation causes the peak in $C_P$ at $T_N$ to split into two distinct peaks. The complexity of the magnetism in CuSb$_2$O$_6$, CoSb$_2$O$_6$, and NiTa$_2$O$_6$ is further demonstrated in the $C_P$ data above $T_N$ by the presence of local magnetic order between $\sim$100 K and $T_N = 8.7$ K, 13.45 and 10.5 K, respectively.\textsuperscript{11–14} In the case of CuSb$_2$O$_6$, $C_P$ exhibits an energy gap below $T_N$, with magnitude $\Delta/k_B = 17.5$ K ($k_B$ is the Boltzmann constant), which is associated with the magnetic order, and leads to the elimination of a linear term in $C_P$ existing above $T_N$.\textsuperscript{11} Such analysis for CoSb$_2$O$_6$ will be reported below, and has yet to be investigated for NiTa$_2$O$_6$. The magnetic susceptibility $\chi$ of these compounds also exhibits behavior expected for one-dimensional spin-chain systems,\textsuperscript{8,11,14,16} with broad peaks in $\chi$ above $T_N$.

Unambiguous identification of the magnetic structure associated with the antiferromagnetism of AB$_2$O$_6$ compounds has been challenging.\textsuperscript{7,15–17} In the case of CuSb$_2$O$_6$, Nakua and Greedan\textsuperscript{17} proposed two magnetic structures based on powder neutron diffraction data. One of these structures is the two-sublattice (or orthogonal) AFM structure, which describes the copper magnetic moments ordered antiparallel along [110] at $z = 0$ and [110] at $z = 1/2$. Gibson et al.\textsuperscript{18} reported neutron diffraction measurements on single crystals and concluded that the moments ordered in a similar manner, but with a slight tilting to account for anisotropy in the magnetic susceptibility between the $a$- and $b$-axes below the Néel temperature. Kato et al.\textsuperscript{16} utilized neutron diffraction on single crystals and determined that the magnetic moments aligned ferromagnetically along [010] with moments of adjacent chains aligned antiparallel, thus forming a magnetic wave vector ($\pi/a$, 0, $\pi/c$). More recent experiments\textsuperscript{19} agree with Kato et al. The latter two investigations appear to be the most detailed, and they are corroborated by magnetic susceptibility\textsuperscript{12} and torque...
magnetometry\textsuperscript{20} data below \(T_N\). It thus appears that the structure obtained by Kato \textit{et al.}\textsuperscript{13} agrees best with the available data. This structural model, however, disagrees with the magnetic structure suggested from calculated spin-exchange constants.\textsuperscript{13} In the case of NiTa\(_2\)O\(_4\), Law \textit{et al.}\textsuperscript{14} determined that the dominant AFM exchange path is along [110] at \(z = 0\) and [110] at \(z = 1/2\) which describes the same AFM two-sublattice structure as above. Ehrenberg \textit{et al.}\textsuperscript{21} on the other hand, reported a different magnetic structure in which the magnetic moments collinearly aligned parallel to [110] (without a sublattice rotated by 90\(^\circ\)). However, the anisotropic MCE\textsuperscript{12} described above is consistent only with the two-sublattice AFM structure.

The subject of the present study is CoSb\(_2\)O\(_6\). It crystallizes\textsuperscript{22} in a tetragonal, trirutile structure with space group \(P4_2/mnm\) and lattice parameters \(a = 4.6495\) Å and \(c = 9.2763\) Å. It is an electrical insulator with electrical conductivity\textsuperscript{23} \(\leq 10^{-7}\) (\(\Omega\) cm\(^{-1}\)) at 295 K. Long-range AFM order occurs below Néel temperature \(T_N = 13.45\) K; this order appears consistent with the two-dimensional Ising model.\textsuperscript{22} The magnetic structure of CoSb\(_2\)O\(_6\) was reported as similar to that of FeTa\(_2\)O\(_6\).\textsuperscript{22} However, two different magnetic structures have been proposed for FeTa\(_2\)O\(_6\),\textsuperscript{9} one of which is identical to the two-sublattice structure introduced above. Our previous report\textsuperscript{12} explored the anisotropy of the magnetic susceptibility of single-crystal CoSb\(_2\)O\(_6\), concluding that the two-sublattice AFM structure seems appropriate for CoSb\(_2\)O\(_6\). Furthermore, the presence of one-dimensional magnetic chains was convincingly revealed through the anisotropic MCE.

In this report, an exploration of the physical properties of single-crystalline CoSb\(_2\)O\(_6\) is presented. The magnetic susceptibility \(\chi\) reveals significant anisotropy along with a broad peak in its temperature dependence that is characteristic of 1D AFM spin-chain systems. Curie-Weiss analysis indicates that the Co\(^{2+}\) ion is in the high-spin state, \(S = 3/2\). The \(\chi(T)\) data are also analyzed with a model for 1D spin-chain systems consisting of \(S = 3/2\) dimers. The results yield a value for the coupling along the 1D chain of \(J_///k_B = -10.603(6)\) K. Heat capacity data reveal a significant loss of magnetic entropy upon cooling below 80 K, which is well above \(T_N = 13.45\) K; this indicates the presence of a substantial amount of local magnetic order above \(T_N\). This local order coalesces into long-range antiferromagnetism at \(T_N\) for which a critical exponent consistent with the three dimensional (3D) Ising model is observed. Thus, the transition at \(T_N\) can be viewed as a crossover from local, probably 1D, to 3D antiferromagnetism. High-resolution thermal expansion measurements are also presented. They exhibit significant anisotropy, including a negative thermal expansion coefficient along the \(c\)-axis below 80 K. Comparison to thermal expansion measurements of non-magnetic ZnSb\(_2\)O\(_6\) allows association of the unusual thermal expansion of CoSb\(_2\)O\(_6\) with its local magnetic order.

II. SAMPLE PREPARATION AND MEASUREMENT DETAILS

Polycrystalline samples were prepared using Co\(_3\)O\(_4\) and Sb\(_2\)O\(_3\). A slight excess (about 5 percent) of Sb\(_2\)O\(_3\) was added to prevent\textsuperscript{22} formation of Co\(_2\)Sb\(_2\)O\(_{15}\). The starting materials were mixed, pelletized, and placed in an alumina crucible; the sample was warmed from 400\(^\circ\)C at 50\(^\circ\)/day to 1050\(^\circ\)C, and held there for 3 days. One regrinding and re-firing was performed to obtain a pure phase, which was confirmed using x-ray diffraction. The crystal structure is tetragonal with lattice parameters that agree with prior work.\textsuperscript{22}

For the single-crystal growth, one gram of CoSb\(_2\)O\(_6\) powder was placed in a 1 cm diameter, 15 cm long quartz tube (1 mm wall thickness) along with 100 mg of TeCl\(_4\). The Cl vapor transports the CoSb\(_2\)O\(_6\) slow down the hot side of the tube to the cool side, where single-crystals form. The Cl vapor transports the CoSb\(_2\)O\(_6\) from the hot side of the tube to the cool side, where single-crystals form. The crystals have the expected crystal structure,\textsuperscript{22} are typically 3 to 5 mg in mass, dark brown in color, and often formed as bicrystals. Bicrystal boundaries were identified during the orienting process, in which Laue x-ray diffraction was employed. The unwanted secondary crystal was removed via polishing.

Magnetic susceptibility and heat capacity were measured using a Quantum Design Physical Properties Measurement System (PPMS). The susceptibility was measured for three crystals (\(m_1 = 3.71\) mg, \(m_2 = 4.74\) mg, and \(m_3 = 5.67\) mg) using a constant 2 kOe magnetic field over a temperature range of 2 to 300 K; field is applied in the same direction as the moment measurement. The data obtained from the three crystals agreed well. Heat capacity was measured on a polycrystalline sample of CoSb\(_2\)O\(_6\) of mass 22.77 mg and on all three single crystals. ZnSb\(_2\)O\(_6\) was utilized as a non-magnetic analog for analysis purposes. Its preparation was reported previously.\textsuperscript{11}

Thermal expansion measurements were performed on samples 1 and 2 (with dimensions \(a \times b \times c\) equal to 1.18 \(\times 0.55 \times 0.92\) mm\(^3\) and 1.20 \(\times 0.85 \times 0.81\) mm\(^3\)) using a dilatometer cell constructed of fused quartz,\textsuperscript{25} which can determine changes in length at a resolution of up to 0.1 Å. Each curve presented herein is composed of about 1800 data points, with a spacing of 0.2 K. The data for the linear thermal expansion were fitted using a method described previously\textsuperscript{26} prior to calculating the thermal expansion coefficient. Thermal expansion data for the two crystals agree well.
III. RESULTS AND ANALYSIS

A. Magnetic Measurements and Analysis

Magnetic susceptibility $\chi$ at $H = 2000$ Oe is shown in Fig. 1. The data were corrected for the temperature-independent diamagnetism associated with the core electrons ($\chi_{dia} = -112 \times 10^{-6}$ emu/mol). They reveal a broad peak, which is typical for systems possessing 1D chains of antiferromagnetically-coupled spins. Below this peak, a transition due to long-range antiferromagnetic order is observed at $T_N = 13.45$ K; this region is enlarged in the inset of Fig. 1. An obvious anisotropy exists between the $a$- and $c$-axes. Cooling in magnetic field (FC) and cooling in zero magnetic field, followed by application of field (ZFC), exhibited no difference in $\chi(T)$. This conflicts with a prior report, where the FC susceptibility differed from the ZFC susceptibility below the broad peak. The authors attributed this behavior to spin-freezing, which must be associated with the polycrystalline nature of the samples.

Analysis of $\chi(T)$ was conducted using the Curie-Weiss equation $\chi = C/(T-\theta) + \chi_0$, where $C$ is the Curie-Weiss constant, $\theta$ is the Curie-Weiss temperature, and $\chi_0$ is a temperature-independent constant. The Curie-Weiss constant is given by

$$C = \frac{Ng^2\mu_B^2J(J+1)}{3k_B} = \frac{N\mu_{eff}^2}{3k_B},$$

where $N$ is the number of moles, $g$ is the Landé g-factor, $\mu_B$ is the Bohr magneton, and $J$ is the total angular momentum. The data were fitted for $T > 130$ K, which is above the region ($T < 80$ K) where local 1D antiferromagnetic order appears (see discussion of heat capacity data below). The fits are shown by the dashed lines in Fig. 2. The values $\mu_{eff} = 4.617(1)\mu_B$ and $\chi_0 = 3.36(3) \times 10^{-4}$ emu/mole Oe for the $a$-axis, and $\mu_{eff} = 4.606(3)\mu_B$ and $\chi_0 = 3.31(6) \times 10^{-4}$ emu/mole Oe for the $c$-axis, were obtained from the fits. The orbital-angular momentum is typically quenched for 3d ions, making $J = S$ in Eq. (1). The observed magnetic moment reveals that the $\text{Co}^{2+}$ ions are in the $S = 3/2$ state with $g_a = 2.384(1)$ and $g_c = 2.379(1)$ for the $a$ and $c$ axes, respectively. Since the values of $\mu_{eff}$ are identical, within error, the single-ion anisotropy is negligible; this is consistent with the minimal variation (about 2%) of Co-O bond-lengths within the CoO$_6$ octahedra, which leads to a nearly-cubic crystal electric field. Deviation from $q = 2.00$ is common for 3d elements with their d-shells more than half full, and is associated with the spin-orbit interaction. A typically observed value for $\mu_{eff}$ of $\text{Co}^{2+}$ with $S = 3/2$ is $4.8\mu_B$, close to what is observed here. For comparison, $\mu_{eff} = 4.62(1)\mu_B$ was reported for a polycrystal. Curie-Weiss temperatures $\theta_a = \theta_b = -22.2$ K and $\theta_c = -44.1$ K were obtained in the fitting. The average of these is similar to $\theta = -32.4$ K reported for a polycrystalline sample. The negative values of $\theta$ indicate antiferromagnetic correlations.

The temperature-independent constant $\chi_0 \approx 3.3 \times 10^{-4}$ emu/mole Oe is attributed to Van-Vleck paramagnetic susceptibility. Its magnitude is comparable to the literature value $\chi_{VV} \sim 4.0 \times 10^{-4}$ emu/mole Oe. A Van-Vleck susceptibility of $\chi_{VV} \sim 9 \times 10^{-3}$ emu/mole Oe was obtained for the Co$^{2+}$ ion from magnetization data for $H > 30$ tesla measured on a sample of Ba$_3$CoSb$_2$O$_9$. But the magnitude seems far too large when compared to this and earlier work.

FIG. 1: Magnetic susceptibility versus temperature for CoSb$_2$O$_9$ at 2000 Oe. The dashed line is a fit using Eq. (2) for $T > 14$ K. The inset shows an expanded view of the data near $T_N = 13.45$ K (vertical dashed line).

A broad peak in $\chi$ is characteristic of 1D spin-chain systems, and is generally modeled with the Bonner-Fisher theory for $S = 1/2$ using the anisotropic Ising-Heisenberg Hamiltonian. Unfortunately, no analogous model exists for spin-chains with $S = 3/2$, due to the computational complexities associated with the additional degrees of magnetic freedom. We have therefore calculated an expression for $\chi_{||}$ (the susceptibility of the magnetic moments measured parallel to the applied field, called here $H_{||}$) for a $S = 3/2$ Ising model by following the method of Carlin for $S = 1/2$ dimers. In this model, the spins have only two orientations, up or down. The eigenvalues of $S_{||}$ for a single $\text{Co}^{2+}$ ion are $+3$, $+1$, $-1$, and $-3$. A dimer, therefore, has a total of 16 possible states. The partition function $Z$ for this system can
easily be written down, and differentiated according to \( M = N k_B T (\partial ln Z / \partial H_t)_T \), to obtain the magnetization \( M \). Differentiation with respect to the magnetic field and taking the low-field limit leads to the final result

\[
\chi_{\parallel} = \frac{Ng^2 \mu_B^2}{2k_BT} \cdot \frac{\frac{3j_1}{e^{\beta H_t}}}{1 + 2e^{\beta H_t} + e^{2\beta H_t}} \cdot \frac{\frac{3j_2}{e^{2\beta H_t}} + 8e^{3j_2}/T + 9e^{6j_2}/T}{1 + 2e^{\beta H_t} + e^{2\beta H_t} + 2e^{3\beta H_t} + e^{4\beta H_t}}.
\]

The parameter \( J_{\parallel} \) represents the coupling energy between the two magnetic moments and the factor of 2 in the denominator is required to refer to a mole of magnetic ions.

The fit using Equation 2 is shown in Fig. 1 as a dashed line. The fit's quality is good, with the exception of the slight offset of the peak. The values \( g_{\parallel} = 2.4442(5) \) and \( J_{\parallel}/k_B = -10.603(6) K \) were obtained. The negative sign indicates antiferromagnetic coupling. The value of \( g \) is comparable to the value obtained from Eq. (1). The magnitude of \( J_{\parallel} \) is comparable to values reported for polycrystalline CoSb\(_2\)O\(_6\) and CoTa\(_2\)O\(_6\), which were stated to be consistent with the anisotropic square planar Ising model.\(^{22}\) It is apparent in Fig. 1 that the peak in \( \chi \) for the \( c \)-axis data occurs at 23.6 K while the peak for the \( a \)-axis data occurs at 34.3 K. This reflects a preference for the locally-ordered magnetic moments (dimers) to lie in the \( a-b \) plane. When \( H \parallel c \), more thermal energy must be removed before the susceptibility drops upon cooling, which would signal the presence of more dimers with spins pointing along \( H \).

\[ \chi = \frac{Ng^2 \mu_B^2}{2k_BT} \cdot \frac{\frac{3j_1}{e^{\beta H_t}}}{1 + 2e^{\beta H_t} + e^{2\beta H_t}} \cdot \frac{\frac{3j_2}{e^{2\beta H_t}} + 8e^{3j_2}/T + 9e^{6j_2}/T}{1 + 2e^{\beta H_t} + e^{2\beta H_t} + 2e^{3\beta H_t} + e^{4\beta H_t}}. \]

(2)

FIG. 2: Plot of \( \chi^{-1} \) versus temperature at 2000 Oe. The dashed lines are linear fits upon which the Curie-Weiss analysis is based. These line were extrapolated to illustrate the \( T \) intercepts.

Magnetization of the crystal with \( m = 4.74 \text{ mg} \) (sample 2) was measured from 0 to 9 tesla at 3 K (see Fig. 3) in order to search for a spin-flop transition, which is observed in CuSb\(_2\)O\(_6\).\(^{11}\) The data reveal a linear trend for \( H \parallel c \). A minor deviation from linearity beginning above 7 tesla for \( H \parallel a \) is observed. The \( a \)-axis data in Fig. 3 contain three separate measurements, for field applied along the [100], [010], and [110] crystallographic directions. The data lie directly on top of one another. The slight deviation at higher fields for the \( H \parallel a \) data may be caused by the known shift in \( T_N \) to lower temperature when an applied field has a component parallel to the spin-chains within one of the sublattices.\(^{12}\) No deviation would be expected for \( H \parallel c \) since no shift in \( T_N \) with \( H \) occurs.

B. Heat Capacity and Thermal Expansion

Measurements and Analysis

The heat capacity of CoSb\(_2\)O\(_6\) is shown in Fig. 4(a). The phase transition at \( T_N = 13.45 \text{ K} \) is clearly visible. Fitting with the equation \( C_P/T = \gamma + \beta T^2 \) for the polycrystalline sample over the range 24 K < \( T < 37 \text{ K} \) yields \( \gamma = 204(1) \text{ mJ/mol K}^2 \) and \( \beta = 0.096(1) \text{ mJ/mol K}^4 \) with a Debye temperature of \( \Theta_D \equiv [(12\pi^4 N_i R)/(5\beta)]^{1/3} = 567(2) \text{ K} \), where \( N_i \) is the number of ions per formula unit and \( R \) is the gas constant. The same analysis for sample 3 yields \( \gamma = 203(4) \text{ mJ/mol K}^2 \), \( \beta = 0.076(3) \text{ mJ/mol K}^4 \) and \( \Theta_D = 613(8) \text{ K} \). Note that CoSb\(_2\)O\(_6\) is an electrical insulator,\(^{23}\) so the \( \gamma \) term is not associated with the presence of conduction electrons. The heat capacity of ZnSb\(_2\)O\(_6\) is also shown in Fig. 4(a); fitting results for these data can be found in Ref. 11. The \( C_P \) data of ZnSb\(_2\)O\(_6\), which is non-magnetic, were subtracted from the CoSb\(_2\)O\(_6\) data in order to isolate the magnetic contributions to the heat capacity; the result, \( \delta C_P \), is plotted in Fig. 4.

An asymmetric peak with a long tail is observed in \( \delta C_P/T \) (Fig. 4(b)), which goes to zero near 80 K, signaling the temperature below which local magnetic order begins to occur. The area under this curve is the magnetic susceptibility. The data lie directly on top of one another. The slight deviation at higher fields for the \( H \parallel a \) data may be caused by the known shift in \( T_N \) to lower temperature when an applied field has a component parallel to the spin-chains within one of the sublattices.\(^{12}\) No deviation would be expected for \( H \parallel c \) since no shift in \( T_N \) with \( H \) occurs.

FIG. 3: Magnetic moment versus magnetic field at \( T = 3 \text{ K} \). The \( c \)-axis data are linear while the \( a \)-axis data deviate slightly from linearity (shown by the dashed line) at high field.

FIG. 4: (a) The phase transition at \( T_N = 13.45 \text{ K} \) is clearly visible. Fitting with the equation \( C_P/T = \gamma + \beta T^2 \) for the polycrystalline sample over the range 24 K < \( T < 37 \text{ K} \) yields \( \gamma = 204(1) \text{ mJ/mol K}^2 \) and \( \beta = 0.096(1) \text{ mJ/mol K}^4 \) with a Debye temperature of \( \Theta_D \equiv [(12\pi^4 N_i R)/(5\beta)]^{1/3} = 567(2) \text{ K} \), where \( N_i \) is the number of ions per formula unit and \( R \) is the gas constant. The same analysis for sample 3 yields \( \gamma = 203(4) \text{ mJ/mol K}^2 \), \( \beta = 0.076(3) \text{ mJ/mol K}^4 \) and \( \Theta_D = 613(8) \text{ K} \). Note that CoSb\(_2\)O\(_6\) is an electrical insulator,\(^{23}\) so the \( \gamma \) term is not associated with the presence of conduction electrons. The heat capacity of ZnSb\(_2\)O\(_6\) is also shown in Fig. 4(a); fitting results for these data can be found in Ref. 11. The \( C_P \) data of ZnSb\(_2\)O\(_6\), which is non-magnetic, were subtracted from the CoSb\(_2\)O\(_6\) data in order to isolate the magnetic contributions to the heat capacity; the result, \( \delta C_P \), is plotted in Fig. 4.

An asymmetric peak with a long tail is observed in \( \delta C_P/T \) (Fig. 4(b)), which goes to zero near 80 K, signaling the temperature below which local magnetic order begins to occur. The area under this curve is the magnetic susceptibility. The data lie directly on top of one another. The slight deviation at higher fields for the \( H \parallel a \) data may be caused by the known shift in \( T_N \) to lower temperature when an applied field has a component parallel to the spin-chains within one of the sublattices.\(^{12}\) No deviation would be expected for \( H \parallel c \) since no shift in \( T_N \) with \( H \) occurs.
spin 3/2. The loss of entropy upon cooling from 80 K to $T_N$ is significant, 5.68 J/mol K (or 49.3% of the theoretical value for $S = 3/2$), which indicates that nearly half of the magnetic moments are engaged in local magnetic order prior to the onset of long-range magnetic order below $T_N$. This is consistent with the modeling of the magnetic susceptibility through Equation 2. A significant amount of local magnetic order above $T_N$ was also observed in CuSb$_2$O$_6$.

The presence of thermal excitations above $T_N$ are evidenced by the linear term in $C_P$. Since this term is not due to conduction electrons, it seems reasonable to assume that its origin lies with magnetic excitations associated with the local magnetic order observed above $T_N$. In comparing the $C_P$ data of CoSb$_2$O$_6$ and CuSb$_2$O$_6$, two main differences arise. First, the observed value of $\gamma$ is significantly larger in CoSb$_2$O$_6$ (203(4) mJ/mol K versus 58.7(7) mJ/mol K). Second, although the linear term in $C_P$ is evidenced by the linear term in $\delta C_P$ (inset of Fig. 4(a)) is not linear over the entire range below $T_N$, and requires a more complicated analysis. The data in this region were fitted with the equation

$$\delta C_P = A_1 T \exp(-\Delta_1/k_B T) + A_2 T^3 \exp(-\Delta_2/k_B T).$$

The first term is associated with the decay of the linear-in-$T$ excitations observed above $T_N$. These are probably due to the regions of the sample that remain unordered below $T_N$. The second term is the dominant one; it represents antiferromagnetic magnons that possess a gap in their excitation spectrum. The constant prefactors $A_1 = 13.3(7)$ mJ/mol K$^2$ and $A_2 = 0.0544(4)$ mJ/mol K$^3$. The energy gaps obtained from the fitting are $\Delta_1/k_B = 1.49(26)$ K and $\Delta_2/k_B = 33.92(9)$ K. The fit is shown in the inset of Fig. 4(a) by the solid line.

Thermal expansion measurements were performed along each of the three axes of sample 1 and sample 2 over a temperature range from 5 to 300 K. The change in sample length $\Delta L$ was normalized to the length at 300 K, $L_{300}$. It is plotted versus $T$ in Fig. 5(a). Measurements along the a and b axes agree well, as expected for a sample with a tetragonal crystal structure. Comparison of the expansions along a and c reveals significant anisotropy, with the expansion along a about 1.75 times larger than the expansion along c over the measured temperature range. A change in slope of $\Delta L/L_{300}$ is apparent at 13.45 K for both axes (see upper insets in Fig. 5(a)). This is associated with the antiferromagnetic phase transition. Since a change in slope is observed, rather than a jump, the phase transition appears to be continuous (second-order) in nature. The feature at $T_N$ along the a-axis is about 33 times larger than the feature along c, indicating that the coupling between the lattice and the magnetic order is stronger within the a-b plane than along c.

![FIG. 4: (a) Heat capacity ($C_P$) for CoSb$_2$O$_6$ and the non-magnetic analog ZnSb$_2$O$_6$. The upper inset shows a natural log versus $1/T$ plot of the difference between the heat capacities of CoSb$_2$O$_6$ and ZnSb$_2$O$_6$ ($\delta C_P$); the solid line is a fit using Equation 3. (b) $\delta C_P/T$ is plotted versus T. The area under this curve is the magnetic entropy. It is shown in the inset.](image)

The thermal expansion coefficients $\mu$ were obtained by taking the temperature derivative of the $\Delta L/L_{300}$ data; they are shown in Fig. 5(b). Also plotted are $\mu$ along a and c for the non-magnetic analog compound ZnSb$_2$O$_6$; note that CoSb$_2$O$_6$ and ZnSb$_2$O$_6$ both have tetragonal crystal structures and their lattice parameters differ by 1.7 % or less. The thermal expansion coefficients of these two compounds have similar values near 300 K, but deviate markedly as the temperature is lowered below $\sim$180 K. This difference must be associated with the presence of the magnetic ions, and the existence of local magnetic order as revealed in the $\Delta S_m$ data in Fig. 4(b).

Thermal expansion in solids results from anharmonic contributions to the elastic potential, with the pair potentials between neighboring atoms playing an important role in this many-body potential. In CoSb$_2$O$_6$, local 1D magnetic order occurs on cooling below $\sim$80 K. This local magnetic order would directly affect the pair potentials in ordered regions of the sample, which in turn could dramatically alter the phonon spectrum, especially given the large fraction of Co ions participating in magnetic order. We believe that the local magnetic order along the Co-O-O-Co chains leads to anharmonicity in some...
lattice vibrations, and the very different behavior of $\mu$ for CoSb$_2$O$_6$ below 180 K when compared to ZnSb$_2$O$_6$. Below ~40 K the thermal expansion coefficients change behavior because such a large proportion of the spins are ordered that the anharmonic contributions reduce upon further cooling, which leads to a decrease in the magnitude of $\mu$. The negative thermal expansion along c is in strong contrast to the behavior along a, and is probably connected to the 1D behavior between $T_N$ and 80 K, and anharmonic lattice vibrations that specifically affect $\mu$ along this direction. CuGeO$_3$ also exhibits$^{39}$ a prominent correlation between thermal expansion and the formation of 1D magnetic correlations.

The antiferromagnetic phase transition appears as a peak in the thermal expansion coefficient, as expected for a continuous phase transition. This temperature region is highlighted in the inset of Fig. 5(b). The peak associated with the phase transition for the c-axis is extremely small. For the a-axis data, a small double-peak is evident in $\mu$, which is associated with a change in the sample warming rate.$^{40}$ The heat capacity in the immediate vicinity of a continuous phase transition can be written as$^{41}$

$$C_p = T \left( \frac{\partial S}{\partial T} \right)_{T_N} + vT\Omega \left( \frac{\partial P}{\partial T} \right)_{T_N}, $$  

(4)

where $S$, $P$, $v$, and $\Omega$ are the molar entropy, pressure, molar volume, and volume thermal expansion coefficient, respectively. The subscript $T_N$ denotes that the equation is valid near the Néel temperature. The molar volume is $v = 6.864 \times 10^{-5}$ m$^3$/mol and $\Omega$ is taken to be the sum of the linear expansion coefficients (2$\mu_a + \mu_c$) near $T_N$. The first term in Eq. (4) is linear. It can be subtracted from $C_P$ to yield $C_P^* = C_P - a - bT$. With $v/\lambda = dT_N/dP$, $C_P^*$ scales with $\lambda\Delta T$. The values $a$, $b$, and $\lambda$ are chosen such that the $\lambda\Delta T$ and $C_P^*$ data have the best possible overlap. This is achieved (see Fig. 6) with $a = 0.2$ J/mol K, $b = -0.06$ J/mol K$^2$, and $\lambda = 1.7 \times 10^5$ J/mol K, which yields $dT_N/dP = 0.40$ K/GPa. We are unaware of any direct measurements of $dT_N/dP$ at this time, with which to compare this value. The good overlap of the $C_P^*$ and $\lambda\Delta T$ in the vicinity of $T_N$ (see Fig. 6) suggests that the phase transition at $T_N$ is continuous.

The sharpness of the peak in $C_P$ in Fig. 5 was observed to be very broad, as illustrated in Fig. 6, where a double-peak is evident; a double-peak was also observed in the polycrystalline sample as well (not shown). Measurement of $C_P$ in magnetic field on single crystals revealed$^{12}$ that field can split the peak in $C_P$ into two peaks, depending upon the orientation of the magnetic field with respect to the crystallographic axes. In this case, since a magnetic field was not present, the appearance of two peaks is probably associated with disorder.

The $C_P^*$ data of sample 3 have been analyzed in the vicinity of the phase transition $T_N$ to determine the heat capacity critical exponent $\alpha$. The singularity in heat capacity around a phase transition originates from a non-analytic term in the thermodynamic free energy and can be asymptotically described$^{41}$ by a function of the form

$$C_P^* = \left( \frac{A_\pm}{\alpha_\pm} \right) |t|^{-\alpha_\pm} + B_\pm + Dt,$$

(5)

where $t$ is the reduced temperature $t \equiv |T - T_N|/T_N$; $A_\pm$, $B_\pm$, and $D$ are constants; and $\alpha_\pm$ is the critical exponent.$^{41,42}$ The subscripts denote values of the parameters above (+) and below (−) $T_N$. The value for $\alpha$ can be determined from the $C_P$ data by plotting $\log(C_P^* - B_\pm - Dt)$ against $\log(t)$ and adjusting fit parameter values until the regions above and below the phase transition become linear, with similar slopes. For a continuous phase transition, $\alpha_+ \approx \alpha_-$. This was achieved over two decades$^{43}$ in $t$ (see the inset of Fig. 6) with $B_+ = -4.5$ J/mol K, $B_- = -45$ J/mol K, $D = 5$ J/mol K, and $T_N = 13.5$ K, resulting in $A_+ = 0.2290(20)$ J/mol K, $A_- = 0.4986(76)$ J/mol K, $\alpha_+ = 0.1062(9)$, and $\alpha_- = 0.100(2)$ (averaging to $\alpha = 0.103(3)$). Data for samples 1 and 3 were used in the analysis. The obtained $\alpha$ value is close to $\alpha = 0.110(1)$, which is associated with the three-dimensional ferromagnetic Ising universality class.$^{44}$ Note that calculations of critical ex-

FIG. 5: (a) Linear thermal expansion normalized to the length at 300 K. The insets reveal the region near $T_N = 13.45$ K. (b) Thermal expansion coefficients found by taking the temperature derivatives of the data in the top panel. The dashed lines reveal the thermal expansion coefficients of the non-magnetic compound ZnSb$_2$O$_6$. The inset is the region near $T_N$. 

ponents for a given universality class usually assume a ferromagnetic model but there is reason to believe that they are also valid for antiferromagnets. Some amplitude ratios are predicted to be universal quantities that should be identical for all systems in a given universality class. For the 3-D Ising model, $A_+ / A_-$ is predicted to be 0.523(9), the obtained value of $A_+ / A_- = 0.459(8)$ is close to that prediction. Similarities to an Ising model are not surprising since Co$^{2+}$ ions provide some of the best examples of Ising systems.

This difference suggests a shorter correlation length associated with the magnetic order in CoSb$_6$, which leads to critical phenomena. The presented analysis is consistent with a continuous transition that is Ising-like. However, the transition’s shape is easily affected by disorder, as revealed in Fig. 6, or the presence of magnetic field. This supports the idea that the coupling between adjacent layers along $c$ is weak and easily disrupted by perturbations or defects because of the 90° rotation of neighboring Co-O-O-Co chains along $c$.

Another important aspect is the presence of a very large linear term in $C_P$, which completely vanishes below $T_N$. This term must be associated with spin excitations in the paramagnetic state, and it seems appropriate to attribute it to the local magnetic order that is present between $T_N$ and 80 K. Unlike CuSb$_2$O$_6$, where a simple spin gap forms below $T_N$, the behavior of $C_P$ for CoSb$_2$O$_6$ indicates the presence of antiferromagnetic magnons, with a gap. Although, however, the magnon term accounts for the majority of the $\delta C_P$ curve below $T_N$, there is a minor residual portion that appears to be associated with unordered regions of the sample, which the analysis of $\Delta S_m$ reveals to be about 34% of the magnetic moments at the lowest measured temperature. The existence of significant magnetic disorder is revealing itself as a characteristic of the low-temperature magnetic ground state of these transition-metal-antimony oxides.

The AFM phase transition in CuSb$_2$O$_6$ was interpreted as a spin-Peierls transition, with the addition that interchain coupling leads to 3D AFM order. We believe that the transition in CoSb$_2$O$_6$ has a similar origin, although here $S = 3/2$ on the transition-metal site. Theory has not yielded a strong conclusion regarding the existence of spin-Peierls transitions in $S = 3/2$ systems, but a qualitative argument has been advanced and the possible existence of spin-dimers is suggested. The spin gap observed in CuSb$_2$O$_6$ was $\Delta/k_B = 17.5$ K, which is about half of the $\Delta_2/k_B$ value reported here. However, the gapped region is more complex here, requiring two terms to obtain a reasonable fit. More work will be required to sort out the origin of these two gaps.

In conclusion, a broad range of temperature is observed where CoSb$_2$O$_6$ exhibits local antiferromagnetic order. This state is described simply as a collection of 1D ordered regions, but within 1D physics may be thought of more properly as a spin-liquid phase. At $T_N = 13.45$ K, a transition to long-range antiferromagnetism occurs. This transition can be viewed as a 1D to 3D transition upon cooling through $T_N$, realized through alignment of the 1D regions, and further alignment of stray magnetic moments. Significant magnetic disorder remains to the lowest measurement temperatures. The transition at $T_N$ appears to be continuous, and consistent with the 3D Ising universality class. The results provide an example of a crossover from 1D to 3D behavior resulting from 3D coupling among 1D magnetic chains of $S = 3/2$ magnetic moments that occurs below $T_N$.
