#### Abstract

The atomic and electronic structures of $60^{\circ}$ glide perfect and $30^{\circ} / 90^{\circ}$ glide partial dislocations in CdTe are studied using combined semi-empirical and density functional theory calculations. The calculations predict that the dislocation cores tend to undergo significant reconstructions along the dislocation lines from the singly-periodic (SP) structures, yielding either doubly-periodic (DP) ordering by forming a dimer or quadruplyperiodic ( QP ) ordering by alternating a dimer and a missing dimer. Charge modulation along the dislocation line, accompanied by the QP reconstruction for the Cd-/Te-core $60^{\circ}$ perfect and $30^{\circ}$ partials or the DP reconstruction for the Cd-core $90^{\circ}$ partial, results in semiconducting character, as opposed to the metallic character of the SP dislocation cores. Dislocation-induced defect states for the $60^{\circ} \mathrm{Cd}-/ \mathrm{Te}$-core are located relatively close to the band edges, whereas the defect states lie in the middle of the band gap for the $30^{\circ} \mathrm{Cd}-/ \mathrm{Te}$-core partial dislocations. In addition to the intra-core charge modulation within each QP core, the possibility of inter-core charge transfer between two different dislocation cores when they are paired together in the same system is discussed. The analysis of the electronic structures reveals the potential role of the dislocations on charge transport in CdTe , particularly in terms of charge trapping and recombination.

## I. INTRODUCTION

Cadmium telluride (CdTe) and its alloy cadmium zinc telluride (CZT) have long been regarded as promising semiconductor materials for high-resolution, room temperature X-ray and $\gamma$-ray detectors, due to their high average atomic numbers, band gaps spanning the 1.4 to 1.7 eV range, and moderately high charge carrier mobilities and lifetimes. ${ }^{1,2}$ However, their ultimate energy resolution has been largely limited by defects formed during crystal growth, including point defects, dislocations, and grain boundaries, because these defects often behave as charge trapping centers for electrons or holes and either induce recombination or delay carrier collection. ${ }^{3-7}$ Among various defects, dislocations are of particular interest in CdTe , as they have been experimentally observed to cause defect states within the band gap and show a strong correlation between their spatial distributions and substantial charge trapping in devices excited by X-rays. ${ }^{7-10}$ However, as dislocations often are found decorated with impurities or Te-rich secondary phases (Te precipitates or inclusions) ${ }^{5,7}$, it is difficult to determine experimentally whether the charge carrier trapping is primarily due to the dislocations themselves or their decorating defects. Thus, theoretical calculations are necessary to elucidate the specific role of dislocations on carrier trapping in $\mathrm{Cd}(\mathrm{Zn}) \mathrm{Te}$, separated from the decorating defects.

Dislocations in a crystal are characterized by slip systems consisting of a slip plane and direction. In a zinc-blende crystal, slip preferentially occurs on close-packed $\{111\}$ planes along a close-packed $\langle 110\rangle$ direction. ${ }^{11}$ One of the common dislocations belonging to the $\{111\}\langle 110\rangle$ slip system is the $60^{\circ}$ perfect dislocation, where the angle between the Burgers vector (corresponding to the slip direction) and the dislocation line is $60^{\circ} .{ }^{12}$ The $60^{\circ}$ perfect dislocation often lowers its elastic strain energy by dissociating into two Shockley $30^{\circ}$ and $90^{\circ}$ partial dislocations with the formation of a stacking fault between them. Due to a low stacking fault energy, ${ }^{13}$ the dissociated partial dislocations are mainly observed in CdTe , but undissociated $60^{\circ}$ dislocations are still
experimentally found. ${ }^{14-17}$ Thus, both undissociated and dissociated dislocations are important to consider in CdTe to understand dislocation-induced defect levels. Also, note that for each dislocation, there are two different core types that are inherently non-stoichiometric (which we call "Cd-core" and "Te-core"), since the cores can be terminated by either Cd or Te atomic columns. The structures we study are inspired by experimentally observed 30 partial dislocation structures in CdTe. ${ }^{14,15,17}$

In this work, we perform both semi-empirical and density functional theory calculations to explore the structural and electronic properties of $60^{\circ}$ perfect and $30^{\circ} / 90^{\circ}$ partial dislocations in CdTe. With different $\{111\}$ slip planes (narrowly spaced glide and widely spaced shuffle planes), undissociated $60^{\circ}$ and dissociated $30^{\circ} / 90^{\circ}$ dislocations belong to either the glide or shuffle set. For the dissociated $30^{\circ} / 90^{\circ}$ partials, the glide set is generally considered the primary type, since low-energy stable stacking faults can only exist in the glideset plane. ${ }^{18}$ For the undissociated $60^{\circ}$ perfect dislocation, the dominant set is less clear, but it is generally believed that both sets are not mutually exclusive and their relative concentrations are dependent on the experimental conditions. ${ }^{18}$ Here, we only consider dislocations of the glide set, since we focus on super-periodic dislocation core reconstructions along the dislocation line direction. The directionality of broken bonds that form the dislocation core lies in the plane perpendicular to the line direction for the shuffle set (on the $\{110\}$ plane), so that reconstructions occur in that plane rather than along the dislocation line; for the glide set, the broken bonds lie nearly on the $\{111\}$ slip planes and many are oriented such that reconstructions along the dislocation line may be favored. ${ }^{19-23}$

For each isolated $60^{\circ}$ perfect and $30^{\circ}$ and $90^{\circ}$ partial dislocation (both Cd-core and Te-core in each case), we first examine dislocation core structures that are periodic with the lattice of the unit cell in the dislocation line direction ("singlyperiodic"). We also find core reconstructions resulting in doubly- and quadruply-periodic ordering along the dislocation line direction and compare their energetics, atomic con-
figurations, and electronic structures with those of the singlyperiodic core. We find the quadruply-periodic reconstructed core structures are energetically the most favorable for the $60^{\circ}$ perfect and $30^{\circ}$ partial dislocations, leading to a preferred charge modulation along the dislocation line for overall neutral cores rather than charged metallic dislocation cores. A similar effect occurs for the $90^{\circ} \mathrm{Cd}$-core partial, but in that case a doubly-periodic core reconstruction that maintains overall neutrality is favored. In addition, we consider the effects of two different dislocation cores existing in the same system and discuss the possibility of inter-core charge transfer. Based on the results, we evaluate the impact of dislocation-induced defects on charge transport in CdTe.

## II. METHODS

We performed both semi-empirical and density functional theory (DFT) calculations to determine the energetics, atomic configurations, and electronic properties of the dislocation cores. Initially, single dislocations were introduced into large orthorhombic cells of $\sim 12,000$ atoms with the $y$-axis parallel to the $[1 \overline{1} 0]$ dislocation line direction and $x$ - and $z$-axes parallel to the $[\overline{1} \overline{1} 2]$ and [111] of the zinc-blende lattice, respectively. Each $60^{\circ}$ perfect dislocation and $30^{\circ}$ and $90^{\circ}$ partial dislocation was constructed with Burgers vector $\frac{1}{2}[0 \overline{1} 1]$, $\frac{1}{6}[1 \overline{2} 1]$, and $\frac{1}{6}[\overline{1} \overline{1} 2]$, respectively. The dimensions of the cell along the $x, y$, and $z$ direction were $20 \times 1 \times 24$, with respect to each unit cell lattice vector. We applied free surface boundary conditions in the $x-z$ plane, while periodic boundary conditions along the $y$ direction to simulate an infinitely long dislocation line.

To relax the large initial dislocation structures, semiempirical calculations using a Stillinger-Weber potential ${ }^{24}$ were carried out using the LAMMPS package ${ }^{25}$ to take into account the long-range strain field around the dislocation cores. Then, a smaller model ( $\sim 150$ atoms) was extracted from the large one for DFT calculations, and each Cd and Te dangling bond at the edge was passivated by a pseudohydrogen atom with a fractional charge of 1.5 or 0.5 electrons, respectively, to ensure charge balance, as shown in Fig. 1. A minimum vacuum separation of $\sim 11 \AA$ was chosen to avoid interaction between replicated cells along the $x$ and $z$ direction. In addition, the smaller cell was quadrupled along the [110] dislocation line direction to examine structural relaxations along that direction, resulting in a model containing $\sim 750$ atoms, including the pseudo-hydrogen atoms.

All DFT calculations were performed using the local density approximation (LDA) ${ }^{26}$ and projector-augmented wave (PAW) approach ${ }^{27}$ as implemented in the VASP code. ${ }^{28} \mathrm{~A}$ plane-wave cutoff energy of 275 eV and a $1 \times 2 \times 1$ MonkhorstPack $k$-point mesh ${ }^{29}$ were used for geometry optimization; for computing the corresponding electronic structure, the cutoff energy and the $k$-point mesh density were increased to 330 eV and a $\Gamma$-centered $1 \times 4 \times 1$ mesh, respectively. The valence electron configurations considered were $4 d^{10} 5 s^{2}$ for Cd and $5 s^{2} 5 p^{4}$ for Te , with the remaining electrons frozen in pseudopotential cores. During the structural relaxations with

FIG. 1. Atomic structure models of the (a) $60^{\circ}$ perfect, (b) $30^{\circ}$ partial, and (c) $90^{\circ}$ partial dislocations for DFT calculations, projecting along the [110] dislocation line direction. All dangling bonds at the edge atoms are passivated by pseudo-hydrogen atoms. The inserted half-plane in (a) and the stacking fault region in (b) and (c) are shaded. The selected core atoms are labeled as A and B. Here, Cd-core dislocations are shown for illustration. Red, gray, and small white balls represent $\mathrm{Cd}, \mathrm{Te}$, and pseudo-hydrogen atoms, respectively.

DFT, the Cd and Te atoms of the outermost layer in the $x-z$ plane were fixed to maintain the long-range strain field calculated from the large Stillinger-Weber-relaxed structures, while all remaining atoms including pseudo-hydrogens were fully relaxed until the residual forces on constituent atoms were smaller than $0.02 \mathrm{eV} / \AA \AA$.

## III. RESULTS

## A. $60^{\circ}$ perfect dislocations

Figure 2 shows the geometries of possible Cd-core $60^{\circ}$ glide dislocations, and the corresponding partial local electronic density of states (PLDOS) are shown in Fig. 3. First, as shown in Fig. 2(a), the core Cd atom $\left(\mathrm{Cd}_{A 1}\right)$ is threefold coordinated and bonded to the $\mathrm{Cd}_{B 1}$ atom with a bond length of $2.65 \AA$, which is considerably shorter than the calculated $\mathrm{Cd}-\mathrm{Cd}$ bond length of $2.88 \AA$ for bulk $\mathrm{Cd} ;{ }^{30}$ in this configuration, $\mathrm{Cd}_{A 1}$ forms a nearly planar configuration with its three neighboring atoms. The core is a singly-periodic (SP) structure and the distance between neighboring $\mathrm{Cd}_{A 1}$ atoms along the dislocation line is $4.54 \AA$; here, SP refers to the structure having a lattice vector along the dislocation line direction that equals a single unit vector of the zinc-blende lattice, as indicated by the dashed rectangular box in Fig. 2(a). According to the PLDOS and partial charge density calculations shown in Fig. 3(a), there is a partially filled defect state near the top of the valence band, which is predominantly derived from $\mathrm{Cd}_{A 1}$ and $\mathrm{Cd}_{B 1}$ states. It is worth noting that before forming the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bond, there are three broken Cd bonds at the core due to the inserted half-plane (one is from $\mathrm{Cd}_{B 1}$ and the other two are from $\mathrm{Cd}_{A 1}$ ), and that forming the bond between $\mathrm{Cd}_{A 1}$ and $\mathrm{Cd}_{B 1}$ stabilizes these dangling bonds; in Fig. 2(a), all Cd and Te atoms except the core atoms are fourfold coordinated with one additional bond (not shown) oriented along the [111] direction. Since each broken Cd bond is associated with 0.5 electrons ( $e$ ) (note that a $\mathrm{Cd}-\mathrm{Te}$ bond is formed approximately by $0.5 e$ from Cd and $1.5 e$ from Te ), the defect state corresponding to the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bonding state is partially occupied

FIG. 2. Optimized configurations of a Cd-core $60^{\circ}$ glide dislocation in the $\{111\}$ glide plane. (a) The singly-periodic (SP) and the (b) doubly-periodic (DP) and (c) quadruply-periodic (QP) core structures along the $[1 \overline{1} 0]$ dislocation line direction. For comparison with the QP structure, the unit cell of SP and DP structure (indicated by the dashed box) is quadrupled and doubled, respectively, in the [11 0$]$ direction. Important core Cd atoms in each unit cell are labeled as A and $B$ with numbers, indicated. Red and gray balls represent Cd and Te atoms, respectively.
by $1.5 e$, as illustrated by the band-decomposed charge density isosurface in Fig. 3(a).

The undercoordinated $\mathrm{Cd}_{A 1}$ atoms drive the SP structure to undergo a reconstruction along the dislocation line by forming a bond between two neighboring $\mathrm{Cd}_{A 1}$ atoms, yielding a doubly-periodic (DP) structure as shown in Fig. 2(b) with an energy gain of $0.34 \mathrm{eV} / \mathrm{nm}$. In the DP structure, the $\mathrm{Cd}_{\mathrm{A1}^{-}}$ $\mathrm{Cd}_{A 2}$ bond length is $2.87 \AA$, while the $\mathrm{Cd}_{A 2}$ also forms a bond with $\mathrm{Cd}_{B 1}$ with a bond length of $2.97 \AA$. As shown in Fig. 3(b), the DP reconstruction enables two three-quarter-filled sates $(2 \times 1.5 e)$ to split into one fully filled (2.0e) and one half-filled (1.0e) state. The defect state associated with $\mathrm{Cd}_{A 1}, \mathrm{Cd}_{B 1}$, and $\mathrm{Cd}_{A 2}$ in a three-center two-electron bond is fully occupied and merges into the valence band. On the other hand, the defect state involved in the $\mathrm{Cd}_{A 2}-\mathrm{Cd}_{B 2}$ bonding lies near the middle of the band gap and is half-filled; with the decreased charge on the $\mathrm{Cd}-\mathrm{Cd}$ bonding state (from $1.5 e$ to $1.0 e$ ), the $\mathrm{Cd}_{A 2}-\mathrm{Cd}_{B 2}$ bond length is noticeably elongated to $2.83 \AA$ compared to $2.65 \AA$ for the SP structure. Similar DP reconstructions along the dislocation line have also been proposed for $60^{\circ}$ dislocations in Si and diamond. ${ }^{19,21}$

Since there are still partially filled states in the band gap, we further examine possible reconstruction to a quadruplyperiodic ( QP ) structure generated initially by combining a dimer and a missing dimer along the dislocation line. After relaxation, the core $\mathrm{Cd}_{A 1}, \mathrm{Cd}_{A 2}$, and $\mathrm{Cd}_{A 3}$ atoms in the QP structure form a trimer along the dislocation line, while $\mathrm{Cd}_{A 4}$ remains threefold coordinated as in the SP core [see Fig. 2(c)]. We also note that the core $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}-\mathrm{Cd}_{A 3}$ trimer exhibits strong interactions with $\mathrm{Cd}_{B 1}$ and $\mathrm{Cd}_{B 2}$ resulting in the formation of two triangular Cd clusters on the $\{111\}$ glide plane, similar to bulk Cd atoms in the hexagonal close packed structure. ${ }^{30}$ On the other hand, the remaining $\mathrm{Cd}_{B 3}$ adopts a nearly planar $s p^{2}$ configuration with its three Te neighbors; such a planar $\mathrm{CdTe}_{3}$ configuration is reminiscent of the atoms surrounding a Te vacancy in CdTe. ${ }^{6,31,32}$ Our calculation predicts that the QP structure is $0.58 \mathrm{eV} / \mathrm{nm}$ lower in energy compared to the SP structure.

FIG. 3. (Left panels) Projected DOS onto the core Cd atoms and (right panels) band-decomposed charge density for the (a) SP (b) DP and (c) QP core structure for the Cd-core $60^{\circ}$ glide dislocation. The energy zero is set to the top of the valence band of the pristine structure without a dislocation, and the Fermi level is indicated by vertical dashed lines; the band gap of the pristine CdTe structure is calculated to be 0.9 eV . The projected DOS onto the Cd atom in the pristine CdTe structure are shown as gray shaded areas for a reference. In the insets, the total DOS are shown by the black curves and the gray shaded areas indicate the total DOS for the pristine CdTe structure. The band-decomposed charge densities of core-related states within the band gap (indicated by asterisks in the total DOS plot in the insets) are plotted as isosurfaces set at $10 \%$ of the maximum value.

As shown in Fig. 3(c), the QP reconstruction converts four three-quarter-filled states $(4 \times 1.5 e)$ into three fully occupied defect states $(3 \times 2.0 e)$. Two occupied defect states lying below the valence band edge are associated with the two Cd triangles $\left(\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}-\mathrm{Cd}_{B 1}\right.$ and $\left.\mathrm{Cd}_{A 2}-\mathrm{Cd}_{A 3}-\mathrm{Cd}_{B 2}\right)$, each of which serves as a three-center/two-electron Cd bond. The remaining occupied $\mathrm{Cd}_{A 4}-\mathrm{Cd}_{B 4}$ bonding state appears slightly above the top of the valence band. The empty anti-bonding states for the three-center/two-electron Cd bonds are situated slightly above the conduction band edge. Of particular note is that the charge density at the QP dislocation core is no longer uniformly distributed along the dislocation line, and rather charge modulation occurs along the dislocation line.

Next, we examine the corresponding configurations of the Te-core $60^{\circ}$ glide dislocations in a similar manner as the Cdcore cases analyzed above. Figure 4(a) shows the SP configuration with the threefold-coordinated $\mathrm{Te}_{A 1}$ atom forming a bond with the $\mathrm{Te}_{B 1}$ atom with a bond length of $2.98 \AA$, while exhibiting a distorted tetrahedral configuration. Since each

FIG. 4. Optimized configurations of a Te-core $60^{\circ}$ glide dislocation in the $\{111\}$ glide plane. (a) The SP (b) DP and (c) QP core structures along the $[1 \overline{1} 0]$ dislocation line direction. Important core Te atoms in each unit cell are labeled as A and B with numbers, indicated. Red and gray balls represent Cd and Te atoms, respectively.
broken Te bond is associated with $1.5 e$, there are $4.5 e$ available at the core before forming the bond between $\mathrm{Te}_{A 1}$ and $\mathrm{Te}_{B 1}$. Our analysis shows that the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond utilizes $2.5 e$, while the remaining $2.0 e$ reside on a lone pair state of $\mathrm{Te}_{A 1}$ that appears slightly below the valence band edge. (The occurrence of a similar lone pair state on a chalcogen atom has been recently suggested for $S$ atoms at the interface between a Si nanoparticle and $\mathrm{ZnS} .{ }^{33}$ ) Among the $2.5 e$ in the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond, $2.0 e$ occupy the bonding state, while the remaining $0.5 e$ partially fills the anti-bonding state located in the middle of the band gap, as shown in Fig. 5(a). Due to partial filling of the anti-bonding state, the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond length is slightly longer than the calculated bulk $\mathrm{Te}-\mathrm{Te}$ single-bond length of 2.90 Å. ${ }^{34}$

With structural relaxation along the dislocation line, the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ dimer is formed in the DP structure, as depicted in Fig. 4(b), with an energy gain of $0.07 \mathrm{eV} / \mathrm{nm}$ with respect to the SP structure. The bond length of $2.89 \AA$ for the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ bond is comparable to the bulk $\mathrm{Te}-\mathrm{Te}$ single-bond length. The relatively small energy gain can be attributed to the stability of the tetrahedral coordination of the threefold $\mathrm{Te}_{A 1}$ atom with the lone pair in the SP structure. The calculated PLDOS in Fig. 5(b) shows that two one-quarterfilled states $(2 \times 0.5 e)$ split into a one-half-filled ( $1.0 e$ ) and a fully empty state $(0.0 e)$. The $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ anti-bonding state, located near the middle of the band gap, is half-filled, increasing the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond length to $3.18 \AA$. On the other hand, the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ anti-bonding state is located slightly above the conduction band edge.

The QP structure is obtained by alternately forming a dimer along the dislocation line of the SP structure, as shown in Fig. 4(c), and is $0.22 \mathrm{eV} / \mathrm{nm}$ lower in energy compared to the SP structure. Note that the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond is broken, while new bonds form with neighboring Cd or Te atoms. The PLDOS in Fig. 5(c) shows that there are one fully filled state and three empty states near the band gap. Evidently, the partial charges associated with the $\mathrm{Te}_{A 3}-\mathrm{Te}_{B 3}$ and $\mathrm{Te}_{A 4}-\mathrm{Te}_{B 4}$ antibonding states are transferred to the newly formed $\mathrm{Te}_{B 1}-\mathrm{Te}_{C 1}$ anti-bonding state, as shown in the band decomposed charge density plot in Fig. 5(c). As a result, the $\mathrm{Te}_{A 3}-\mathrm{Te}_{B 3}$ and $\mathrm{Te}_{A 4}{ }^{-}$ $\mathrm{Te}_{B 4}$ bonds have nearly single-bond character with lengths of $2.81 \AA$ and $2.82 \AA$, respectively.

FIG. 5. (Left panels) Projected DOS onto the core Te atoms and (right panels) band-decomposed charge density for the (a) SP (b) DP and (c) QP core structure for the Te-core $60^{\circ}$ glide dislocation. The energy zero is set to the top of the valence band of the pristine structure without a dislocation, and the Fermi level is indicated by vertical dashed lines. The projected DOS onto the Te atom in the pristine CdTe structure are shown as gray shaded areas for a reference. In the insets, the total DOS are shown by the black curves and the gray shaded areas indicate the total DOS for the reference dislocationfree CdTe structure. The band-decomposed charge densities of corerelated states within the band gap (indicated by asterisks in the total DOS plot in the insets) are plotted as isosurfaces set at $10 \%$ of the maximum value.

Based on our calculations, the QP reconstructions are predicted to be the most stable for both the Cd-core and Te-core $60^{\circ}$ glide dislocations, among the three core configurations examined in this work. (Since the electron pairing drives the QP reconstructions, larger periodicities are not expected to occur; the local structural motifs in the QP configurations therefore should represent any longer-range non-periodic arrangement along the dislocation line.) For the QP-reconstructed Cd-core $60^{\circ}$ glide dislocation, the absence of any deep defect states suggests that the Cd-core dislocations might not act as charge trap or recombination centers. However, the QPreconstructed Te-core $60^{\circ}$ glide dislocation exhibits empty deep gap states associated with the core $\mathrm{Te}-\mathrm{Te}$ bond, which can trap electrons and deteriorate charge transport, unlike the case for the Cd-core dislocations.

FIG. 6. Optimized configurations of a Cd-core $30^{\circ}$ partial dislocation in the $\{111\}$ glide plane. Important core Cd atoms in each unit cell are labeled as A with numbers, indicated. Red and gray balls represent Cd and Te atoms, respectively.

## B. $\mathbf{3 0}^{\circ}$ partial dislocations

Here, we investigate the core configurations and the electronic structures of the $30^{\circ}$ glide partial dislocation, which is one of the two partials from dissociation of the $60^{\circ}$ glide dislocation. First, for the Cd-core case, the geometry of the SP structure is presented in Fig. 6(a). The core $\mathrm{Cd}_{A 1}$ atom is threefold coordinated and possesses a $s p^{2}$-like configuration with bond angles of nearly $120^{\circ}$. As shown in Fig. 7(a), the defect state appears very close to the bottom of the conduction band and is hybridized with the largely dispersed conduction band edge. Thus, the $0.5 e$ from the one broken Cd bond from $\mathrm{Cd}_{A 1}$ fills the bottom of the conduction band, and the corresponding charge spreads over many Cd sites [see Fig. 7(a)] near $\mathrm{Cd}_{A 1}$. The results for the geometries and electronic structures of the SP structure are very similar to those from previous studies. ${ }^{14,35}$

When two Cd atoms form a bond along the dislocation line, the Cd-core SP structure reconstructs to the DP structure shown in Fig. 6(b) with an energy gain of $0.24 \mathrm{eV} / \mathrm{nm}$. As depicted in Fig. 6(b), the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}$ bond length is $2.87 \AA$, which is very close to the calculated $2.88 \AA$ in bulk $\mathrm{Cd} .{ }^{30}$ The calculated PLDOS in Fig. 7(b) shows that there is a one-halffilled state (1.0e) in the middle of the band gap. This defect state corresponds to the bonding state of the $\mathrm{Cd}-\mathrm{Cd}$ dimer as also evidenced by the localized charge on the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}$ bond shown in Fig. 7(b).

We find that the Cd-core DP structure can further reconstruct to a QP structure with undimerized core Cd atoms along the dislocation line as shown in Fig. 6(c), with an energy gain of $0.15 \mathrm{eV} / \mathrm{nm}$ compared to the DP structure $(0.39 \mathrm{eV} / \mathrm{nm}$ lower in energy than the SP structure). According to the PLDOS, the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}$ bond-related state lies in the middle of the band gap and $2.0 e$ occupy this defect state, while no other defect states appear within the band gap. This indicates that the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{A 2}$ bonding state becomes fully occupied by additionally donated $0.5 e$ from each $s p^{2}$-like $\mathrm{Cd}_{A 3}$ and $\mathrm{Cd}_{A 4}$ atom [see the isosurface of the band-decomposed charge density in Fig. 7(c)], resulting in the shortened $\mathrm{Cd}_{A 1}-$ $\mathrm{Cd}_{A 2}$ bond length of $2.65 \AA$. Similar structural relaxation also has been suggested for the Te vacancy in CdTe, in which the four threefold-coordinated Cd atoms resulting from the missing Te atom reconfigure to form one $\mathrm{Cd}-\mathrm{Cd}$ bond leaving two

FIG. 7. (Left panels) Projected DOS onto the core Cd atoms and (right panels) band-decomposed charge density for the (a) SP (b) DP and (c) QP core structure for the Cd-core $30^{\circ}$ glide dislocation. The energy zero is set to the top of the valence band of the pristine structure without a dislocation, and the Fermi level is indicated by vertical dashed lines. The projected DOS onto the Cd atom in the pristine CdTe structure are shown as gray shaded areas for a reference. In the insets, the total DOS are shown by the black curves and the gray shaded areas indicate the total DOS for the reference dislocationfree CdTe structure. threefold-coordinated Cd atoms with $s p^{2}$ configuration. ${ }^{31}$
In Fig. 8, the core configurations for the Te-core $30^{\circ}$ glide partial dislocation are presented. In the SP structure, the threefold-coordinated $\mathrm{Te}_{A 1}$ exhibits a trigonal pyramidal configuration with its neighboring Cd atoms. The PLDOS in Fig. 9(a) demonstrates that the defect state lies just above the top of the valence band and is partially empty since only $1.5 e$ are contributed from one broken $\mathrm{Te}_{A 1}$ bond (corresponding equivalently to a 0.5 hole state). The partially empty state is substantially localized on the $\mathrm{Te}_{A 1}$ atom with mainly $p$-like character. As shown in the band decomposed charge density plot in Fig. 9(a), this state is oriented perpendicularly to the plane of neighboring three Cd atoms; this result is similar with a previously reported calculation for Te -core $30^{\circ}$ glide partial dislocations. ${ }^{35}$ Also, a similar feature has been suggested for the Si or C core atoms of the $30^{\circ}$ glide partial dislocations in SiC. ${ }^{36}$

With $\mathrm{Te}-\mathrm{Te}$ dimer formation along the dislocation line, the DP structure in Fig. 8(b) is formed with an energy gain of $0.15 \mathrm{eV} / \mathrm{nm}$ over the SP structure. Here, $3.0 e$ in the $\mathrm{Te}-$

FIG. 8. Optimized configurations of a Te-core $30^{\circ}$ partial dislocation in the $\{111\}$ glide plane. Important core Te atoms in each unit cell are labeled as A with numbers, indicated. Red and gray balls represent Cd and Te atoms, respectively.

Te bond give rise to a half-filled anti-bonding state as well as a fully occupied bonding state, resulting in a substantially longer $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ bond length of $3.34 \AA$ compared to the bulk $\mathrm{Te}-\mathrm{Te}$ single-bond length of $2.90 \AA$. As shown in Fig. 9(b), the half-filled anti-bonding state lies above the valence band edge and the charge is largely localized on the $\mathrm{Te}-\mathrm{Te}$ dimer along the dislocation line. The partial occupancy of the $\mathrm{Te}-\mathrm{Te}$ anti-bonding state can be removed by alternating the dimer formation along the dislocation line as shown in Fig. 8(c). In this QP structure, the energy gain is $0.29 \mathrm{eV} / \mathrm{nm}$ with respect to the DP structure $(0.43 \mathrm{eV} / \mathrm{nm}$ with respect to the SP structure), and the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ bond length of $2.87 \AA$ is close to the bulk single-bond length. This is associated with a charge redistribution between the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ dimer and the threefold-coordinated $\mathrm{Te}_{A 3}$ and $\mathrm{Te}_{A 4}: 1.0 e$ on the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ anti-bonding state goes to the partially filled $5 p$ orbitals of threefold-coordinated $\mathrm{Te}_{A 3}$ and $\mathrm{Te}_{A 4}$, resulting in fully occupied $5 p$ lone pair orbitals. Thus, the $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ anti-bonding state is fully empty as depicted in Fig. 9(c) and is pushed toward the conduction band edge. On the other hand, the fully occupied $\mathrm{Te}_{A 1}-\mathrm{Te}_{A 2}$ bonding state and the $5 p$ lone pair states of $\mathrm{Te}_{A 3}$ and $\mathrm{Te}_{A 4}$ lie within the valence band. With the fully occupied $5 p$ lone pair orbitals, the threefold-coordinated $\mathrm{Te}_{A 3}$ and $\mathrm{Te}_{A 4}$ become more pyramidal than the partially occupied $\mathrm{Te}_{A 1}$ in the SP configuration.

Overall, our calculations predict that the QP configuration is energetically the most favorable one compared to the DP and SP configurations for both the Cd - and Te -core $30^{\circ}$ partial dislocations. It should be noted that core reconstruction for the $30^{\circ}$ partial dislocation has been well studied in Si and SiC , for which the DP structure was suggested as the most probable core configuration. ${ }^{21,22,36}$ The reason that QP configurations are favored instead in CdTe can largely be attributed to the different number of valence electrons per atom in group II-VI $v s$. group IV compounds and the more highly polar bonds in II-VI compounds.

## C. $90^{\circ}$ partial dislocations

Next, we examine the $90^{\circ}$ glide partial dislocation, which is the other partial associated with dissociation of the $60^{\circ}$ glide dislocation, in addition to the $30^{\circ}$ partial. The geometries and

FIG. 9. electronic structures of the Cd-core $90^{\circ}$ partial dislocations are shown in Figs. 10 and 11, respectively. For the Cd-core SP structure, there are two possible geometries, distinguished by the core Cd atoms $\left(\mathrm{Cd}_{A 1}\right.$ and $\left.\mathrm{Cd}_{B 1}\right)$ being either "quasi-
 try as in Fig. 10(a) or fourfold coordinated with broken mir-
ror symmetry as in Fig. 10(b); similar symmetric and asymmetric SP structures for the $90^{\circ}$ glide partial dislocation have been reported in $\mathrm{Si},{ }^{37} \mathrm{SiC},{ }^{22}$ and diamond. ${ }^{21}$ In the symmetric structure, all the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bonds are equivalent with length $3.08 \AA$, while they are split into a short and a long bond with lengths $2.79 \AA$ and $4.21 \AA$ in the asymmetric structure.

As shown in Fig. 11, the PLDOS for both SP structures show a half-filled state in the middle of the band gap ( $0.5 e$ from each broken bond associated with a core Cd atom). According to the band-decomposed charge density plots, the charge corresponding with this gap state is largely delocalized over the core Cd atoms for the symmetric structure, while it becomes more localized and resides on the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bonding state for the asymmetric structure. Our calculation predicts that the Cd-core asymmetric SP structure is slightly more stable than the symmetric one by $0.04 \mathrm{eV} / \mathrm{nm}$, but such a small energy difference suggests no strong preference between these two SP structures. This result is in contrast to group-IV semiconductors, where the asymmetric SP structure is energetically much more favorable than the symmetric one; ${ }^{21,22,37}$ this difference in behavior is partly due to the stronger covalent bonding interaction between group-IV atoms than between Cd atoms and also because the bonding state is fully occupied for the asymmetric dislocations in group-IV compounds since each core atom contains $1.0 e$ from the broken bonds. The fully occupied bonding state of the asymmetric SP structure in group-IV semiconductors also yields a large energy gain, unlike the partially occupied bonding state of the Cdcore asymmetric structure in CdTe.

We find that the SP structure can undergo reconstruction into the DP structure by introducing alternating $\mathrm{Cd}_{A}-\mathrm{Cd}_{B}$ bonds with an energy gain of $0.39 \mathrm{eV} / \mathrm{nm}$. As illustrated in Fig. 10(c), the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bond length is shortened in the DP structure (to $2.64 \AA$ ) compared to that in the SP asymmetric structure ( $2.79 \AA$ ), indicating a stronger bonding interaction in the DP structure. On the other hand, the $\mathrm{Cd}_{A 2}$ and $\mathrm{Cd}_{B 2}$ atoms are widely separated, and each of these Cd atoms exhibits a nearly planar configuration with the three neighboring Te atoms. The PLDOS in Fig. 11(c) reveals that the $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bonding state, which lies in the middle of the band gap, is fully occupied by the donated charge ( $1.0 e$ ) from the $s p^{2}$-like $\mathrm{Cd}_{A 2}$ and $\mathrm{Cd}_{B 2}$. We point out that our calculated DP structure is quite different from the suggested DP structures in groupIV and III-V semiconductors, ${ }^{21,23}$ in CdTe , the DP structure we find is $0.44 \mathrm{eV} / \mathrm{nm}$ lower in energy than the structure analogous to that found in group-IV and III-V semiconductors. ${ }^{38}$ Such distinct DP structure for the Cd-core $90^{\circ}$ partial dislocations can be largely attributed to the ease of formation of the $s p^{2}$-like Cd configuration by donating $0.5 e$ to the adjacent half-filled $\mathrm{Cd}-\mathrm{Cd}$ bonding state.

We further consider possible QP core reconstructions for the Cd-core $90^{\circ}$ partial, but there is no energy gain in this case for quadruple periodicity compared to the double periodicity, unlike for the $60^{\circ}$ and $30^{\circ}$ cases. Since the Cd-core $90^{\circ}$ partial in the DP structure does not have a partially filled gap state, there is no driving force for further QP core reconstruction, further demonstrating the strong correlation between core reconstructions and the electronic structure.

FIG. 11. (Left panels) Projected DOS onto the core Cd atoms and (right panels) band-decomposed charge density for the (a) symmetric SP (b) asymmetric SP and (c) DP core structure for the Cd-core $90^{\circ}$ glide dislocation. The energy zero is set to the top of the valence band of the pristine structure without a dislocation, and the Fermi level is indicated by vertical dashed lines. The projected DOS onto the Cd atom in the pristine CdTe structure are shown as gray shaded areas for a reference. In the insets, the total DOS are shown by the black curves and the gray shaded areas indicate the total DOS for the reference dislocation-free CdTe structure. The band-decomposed charge densities of core-related states within the band gap (indicated by asterisks in the total DOS plot in the insets) are plotted as isosurfaces set at $10 \%$ of the maximum value.

Finally, the core configuration for the Te -core $90^{\circ}$ partial dislocation is shown in Fig. 12. In the symmetric SP structure, the distances between the $\mathrm{Te}_{A 1}$ and $\mathrm{Te}_{B 1}$ are all equivalent with length $3.58 \AA$. The PLDOS in Fig. 12 shows that there is a partially empty defect state near the top of the valence band. The corresponding band-decomposed charge density plot shows that the defect state is predominantly derived from the partially empty $5 p$ orbitals of the threefold-coordinated $\mathrm{Te}_{A 1}$ and $\mathrm{Te}_{B 1}$. Each broken Te bond contains $1.5 e$ (equivalent to 0.5 hole).

We also constructed the asymmetric SP structure (not shown) by breaking the symmetry across the [11 0$]$ mirror plane, as for the Cd-core, but the difference in structure from the symmetric one is very minor for the Te-core, with only slightly different $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ long-bond and short-bond distances of $3.50 \AA$ and $3.67 \AA$. Accordingly, the electronic structure and energy of the asymmetric SP is very similar to that of the symmetric one for the Te-core. Our calculations predict that the symmetric SP is energetically slightly more favorable than the asymmetric one, which can be understood by the anti-

FIG. 12. (Left panel) Projected DOS onto the core Te atoms and (right panel) band-decomposed charge density for the symmetric SP core structure for the Te-core $90^{\circ}$ glide dislocation. The energy zero is set to the top of the valence band of the pristine structure without a dislocation, and the Fermi level is indicated by vertical dashed lines. The projected DOS onto the Te atom in the pristine CdTe structure is shown as gray shaded areas for a reference. In the insets, the total DOS are shown by the black curves and the gray shaded areas indicate the total DOS for the reference dislocation-free CdTe structure. The band-decomposed charge density of core-related states within the band gap (indicated by asterisks in the total DOS plot in the insets) is plotted as isosurfaces set at $10 \%$ of the maximum value.
bonding nature of the $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ bond.
For the Te-core DP structures, we searched for core reconstructions associated with redistributed partial core charges, in analogy to the Te-core $30^{\circ}$ dislocations, where partial charge from the anti-bonding state of one of the $\mathrm{Te}_{A}-\mathrm{Te}_{B}$ goes to the partially filled $5 p$ orbitals of the other $\mathrm{Te}_{A}$ and $\mathrm{Te}_{B}$ pair. However, in the Te-core $90^{\circ}$ partial, steric inhibition of the fully occupied $5 p$ orbitals of the $\mathrm{Te}_{A}$ and $\mathrm{Te}_{B}$ atoms, which face each other, prevents such a DP reconstruction from occurring. We also searched for other possible DP and QP reconstructions of the Te-core $90^{\circ}$ dislocation, but the symmetric SP structure always is predicted to be energetically the most favorable, although the possibility of core reconstructions with larger periodicities or different stoichiometries cannot be precluded. However, a similar trend has been reported for GaAs , in which for the As-core $90^{\circ}$ partial dislocations, the SP structure is energetically more favorable than the DP structure, whereas the DP structure is predicted to be more stable than the SP for the Ga-core $90^{\circ}$ partial dislocation. ${ }^{23}$ Thus, our calculations suggest that the Te-core $90^{\circ}$ partial dislocation might show metallic behavior along the dislocation line, unlike the other dislocations considered in this work.

## IV. DISCUSSION

We have shown that core reconstructions along the dislocation line are energetically favorable for all isolated $\mathrm{Cd}-/ \mathrm{Te}-$ core $60^{\circ}$ perfect, $30^{\circ}$ partial, and Cd-core $90^{\circ}$ partial dislocations in CdTe , while the Te-core $90^{\circ}$ partial remains as the SP structure without core reconstruction along the dislocation line. The driving force for these reconstructions seems to be strongly correlated with the partially occupied core states in the SP structures, which render these dislocations metallic. Considering a dislocation as a one-dimensional (1-D)

Inter-core charge transfer Intra-core charge modulation
(a)
(b)

FIG. 13. Schematic representations of the (a) inter-core charge transfer model and (b) intra-core charge modulation model for the system having both Cd-core and Te-core $30^{\circ}$ glide dislocations. The red and blue shaded area indicate charge accumulation and depletion, respectively, as a result of (a) the charge transfer from the Cd-core to the Te-core and (b) charge modulation accompanied by the QP core reconstruction within each core. Red and gray balls represent Cd and Te atoms, respectively.
like chain, such metallic behavior along the dislocation line might be unstable and a symmetry breaking that opens the band gap would be preferred, which is similar to a conjugated polymer chain that is often subject to the Peierls-like instability. ${ }^{39,40}$ For reference, the calculated band structures for the $60^{\circ}$ perfect (in Fig. S1 and S2), $30^{\circ}$ partial (in Fig. S3 and S4), and $90^{\circ}$ partial (in Fig. S5) dislocations are presented in Supplementary Material. ${ }^{41}$ Since the SP core states are one-quarter-filled (for the Te-core $60^{\circ}$ and the Cd-core $30^{\circ}$ partial) or three-quarter-filled (for the Cd-core $60^{\circ}$ and the Tecore $30^{\circ}$ partial) as presented in our PLDOS analysis, quadrupling the period leads to one or three fully occupied states, respectively. Indeed, our calculations show that for the the $60^{\circ}$ perfect and $30^{\circ}$ partial, the QP structures combine a dimer (or trimer) and a missing dimer to exhibit semiconducting characters with a modulation of the electronic density along the dislocation line. It is worth noting that formation of tetramers along the dislocation line, which might be another possible quadruply-periodic reconstruction, is highly unlikely in CdTe due to the large distance between core atoms. We also considered a possible spin ordering for the partially occupied core states in the SP structures, but it turns out that the energy of the spin-ordered SP structure is considerably higher than that of the charge-modulated QP structure for all dislocations, suggesting that spin ordering is not favorable.

Since the dislocation cores are non-stoichiometric (each Cd-core and Te-core contains excess Cd and Te atoms, respectively), the absolute formation energy of each core structure depends on the growth conditions, which determine the chemical potentials of Cd and Te atoms. Thus, the relative concentrations of Cd -core and Te-core dislocations are effected by different growth conditions; that is, Cd-core dislocations would be more favored in Cd-rich environments, and vice versa. However, the relative stabilities among the SP, DP, and QP structures for a given core type are less sensitive to the growth conditions, since they all have the same number of atoms.

In reality, different dislocations coexist in the same system, and the possibility of charge transfer between Cd -core and Te core dislocations must be evaluated, especially for the metallic SP cores. In our calculations, when the SP Cd-core and Tecore $60^{\circ}$ dislocations are paired together in the same system, charge transfer does occur from the Te-core (partially occupied $\mathrm{Te}_{A 1}-\mathrm{Te}_{B 1}$ anti-bonding states) to the Cd-core (partially empty $\mathrm{Cd}_{A 1}-\mathrm{Cd}_{B 1}$ bonding states). However, the total energy of this charge transfer model is still considerably higher by $0.80 \mathrm{eV} / \mathrm{nm}$ than the charge modulation model having both QP cores in the same system; for the QP cores, the electronic states of each core remain essentially the same when both Cdcore and Te-core coexist in the same system as in the isolated cases. Thus, charge modulation within the cores along the dislocation lines and the accompanying QP reconstruction would be dominant for $60^{\circ}$ dislocations.

For the $30^{\circ}$ partial dislocations, we find that the energy of the charge transfer model between unreconstructed (SP) Cdand Te-cores [Fig. 13(a)] is comparable to the energy of the charge modulation model with each core QP reconstructed [Fig. 13(b)], using DFT-LDA. However, with LDA for the intra-core charge modulation model, there is substantial overlap between the defect energy levels of the occupied Cd-core state and the unoccupied Te-core state within the band gap, leading to partially occupied Cd-core and Te-core states; this arises because the defect level positions within the band gap are very similar for the isolated QP reconstructed $30^{\circ} \mathrm{Cd}$-core and Te-core partial dislocations, as shown in Fig. 7(c) and Fig. 9(c). Since DFT-LDA may incorrectly predict the positions of defect levels due to the underestimation of the band gap, we further carried out hybrid-DFT calculations using the HSE06 functional ${ }^{42}$ to better describe the defect level positions for the isolated QP reconstructed $30^{\circ} \mathrm{Cd}$-core and Te core partial dislocations and more accurately evaluate the energy difference between the charge transfer and charge modulation models. ${ }^{43}$ Using the hybrid HSE06 functional, a calculated band gap of 1.6 eV was obtained, and the occupied defect state is located in the middle of the band gap for the isolated QP reconstructed Cd-core partial dislocation, while the empty defect state lies $\sim 0.3 \mathrm{eV}$ below the conduction band edge for the Te-core partial dislocation. Thus, with the considerable difference ( $\gtrsim 0.5 \mathrm{eV}$ ) between the occupied Cdcore state and the empty Te-core state in the isolated systems, no overlap between these two states is expected in the combined system and complete charge modulation within each core would occur, suggesting that the energy of the intra-core charge modulation model from the DFT-LDA calculation for the $30^{\circ}$ case is considerably underestimated. ${ }^{44}$

For the $90^{\circ} \mathrm{Te}$-core partial dislocation, no core reconstruction is found along the dislocation line, even though a partially occupied defect state exists, unlike the other cases studied. A possible explanation for this anomaly is that the electronic energy gain from charge redistribution is less than the strain energy cost associated with the reconstruction in this case.

In addition, the charge transfer model is only valid when the concentrations of Cd -core and Te -core dislocations are equal, and this condition may be hardly satisfied in real materials, which are usually off-stoichiometric (particularly for
melt-grown material, which is ordinarily grown intentionally Te-rich). Thus, intra-core charge modulation with QP reconstructed cores is more likely to occur than inter-core charge transfer for both $60^{\circ}$ perfect and $30^{\circ}$ partial dislocations.

Further, possible charging effects should be considered for the stabilities of the core configurations, especially for the SP structures of the partial dislocations. Since those Cd-core (Tecore) partials exhibit shallow donor (acceptor) characteristics, respectively, an adequately charged SP structure would be energetically more favorable than the neutral SP structure for intrinsic conditions of the Fermi level. The relative stability of the charged SP structure compared to the neutral QP (or DP) structure would strongly depend on the Fermi level position. For example, for the 30 partials, intra-core charge modulation (representing neutral QP structures) is energetically slightly more favorable than inter-core charge transfer (representing charged SP structures), which suggests that neutral Cd-core/Te-core QP structures would be more stable than positively charged Cd-core and negatively charged Te-core SP structures for intrinsic conditions. For radiation detector applications, the material is highly resistive and intrinsic conditions prevail.

Finally, we note that for the $30^{\circ}$ partial dislocations, although the core atoms exhibit relatively large displacements along the dislocation line direction in the QP reconstructions compared to the SP cases, the atomic displacements projected onto the cross-sectional planes normal to the dislocation line are less than $0.2 \AA$. Thus, it would be extremely difficult to directly observe the core reconstructions experimentally, for example, with scanning transmission electron microscopy (STEM) down the dislocation line direction, even for a state-of-the-art aberration-corrected microscope. ${ }^{14}$ Figure S6 in Supplemental Material includes STEM simulations that demonstrate the subtle, extremely difficult to resolve contrast expected for the QP cores compared to the SP cores. ${ }^{45}$

## v. CONCLUSIONS

We calculated the structural and electronic properties of dislocation cores for $60^{\circ}$ glide perfect, $30^{\circ}$ and $90^{\circ}$ glide partial dislocations in CdTe. Semi-empirical calculations were initially carried out for large dislocation models to take into account the long-range strain fields around the dislocation cores, while density functional theory (DFT) calculations were performed on smaller models extracted from the initial structures to examine core reconstructions and the associated electronic structures. For each isolated dislocation core, the singly-periodic (SP) and doubly-periodic (DP) and quadruplyperiodic (QP) core configurations along the dislocation line were considered for each of the $60^{\circ} \mathrm{Cd} / / \mathrm{Te}$-core perfect and the $30^{\circ}\left(90^{\circ}\right) \mathrm{Cd}-/ \mathrm{Te}$-core partial dislocations. The SP cores exhibit metallic characters along the dislocation line direction with partially occupied defect states in the band gap, however this 1-D like metallic state is highly unstable against lattice distortions along the dislocation line, in analogy with the Peierls distortion of 1-D crystal. For the $60^{\circ}$ perfect and $30^{\circ}$ partial dislocations, we find that QP reconstructions along the
dislocation line consisting of a dimer and a missing dimer in a pair are energetically the most favorable for all dislocations considered in this work. For the $90^{\circ}$ partial dislocations, the Cd-core one prefers to be DP reconstructed, while the Te-core remains as the symmetric SP structure. The driving force for the core reconstruction can be attributed to the resulting charge modulation along the dislocation line, which produces a semiconducting character for the defect. For the QP reconstructed $60^{\circ}$ Cd-core, the fully occupied dislocationinduced defect states lie near the valence band edge and the absence of deep defect states suggest the $60^{\circ} \mathrm{Cd}$-core might not strongly trap charge carriers. For the QP reconstructed $60^{\circ} \mathrm{Te}$-core, in addition to occupied states close to the valence band edge, there are empty states below the conduction band edge, which could affect charge transport by trapping electrons. For the $30^{\circ} \mathrm{Cd}$-core (Te-core) partial dislocation a fully occupied (empty) deep defect state appears. Accordingly, it is expected that the $30^{\circ} \mathrm{Cd}$-core and $30^{\circ} \mathrm{Te}$-core partial dislocations could considerably deteriorate charge transport by trapping charge carriers and inducing recombination. For the $90^{\circ}$ Cd-core partial dislocation, a fully occupied defect state exist in the middle of the band gap, while the $90^{\circ} \mathrm{Te}$-core induces partially empty defect state near the valence band top. Lastly,
we compare the energetics between inter-core charge transfer and intra-core charge modulation when two different cores are paired together. For the $60^{\circ}$ cores, when a Cd-core and Te-core are paired together they strongly prefer to maintain intra-core charge modulation with individual QP reconstructions rather than transfer charge between them. However, the energetics for the intra-core charge modulation compared to inter-core charge transfer are very close for the $30^{\circ} \mathrm{Cd}-/ \mathrm{Te}-$ cores, although in real material, the intra-core charge modulation should be more likely due to constraints on the inter-core charge transfer occurring.

## ACKNOWLEDGMENTS

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344, with support from the DOE National Nuclear Security Administration Office of Defense Nuclear Nonproliferation Research and Development PDP WMS Team (project LL13-MatModelRadDetect-PD3YJ).
