We have systematically investigated magnetic properties of La and Co substituted SrFe$_{12}$O$_{19}$ using single crystals. By utilizing travelling solvent floating zone technique, we have grown single crystals over wide range of substitution content, and examined their saturation moments and magnetocrystalline anisotropy. With increasing content of La and Co, saturation moment at 300 K monotonically increases. The increment of magnetocrystalline anisotropy is almost proportional to the content of Co. In addition, further La substitution also enhances magnetocrystalline anisotropy, which demonstrates that Fe$^{2+}$ plays an important role to enhance magnetocrystalline anisotropy.

We have analyzed magnetocrystalline anisotropy energy as a function of substitution content, and elucidate the effects of Co$^{2+}$ and Fe$^{2+}$.

I. INTRODUCTION

The hexagonal ferrites that have the magnetoplumbite (M-type) structure are important materials for permanent magnets. Since the discovery of M-type hexaferrites$^4$, they have attracted much attention$^2$. Because of their competitive price and easy preparation in comparison with other magnetic materials, they have been extensively used in applications such as electronics, household appliances and communications. They are ferrimagnets with high coercivity, which originates from high magnetocrystalline anisotropy with a easy magnetization axis. Many attempts have been made to improve their magnetic properties.$^3,4$ Among them, the latest breakthrough is based on partial substitutions with La and Co, which are expressed as a Sr$_{1-x}$La$_x$Fe$_{12-x}$Co$_x$O$_{19}$ chemical formula.$^5$

All the Fe ions in the strontium hexaferrite SrFe$_{12}$O$_{19}$ are trivalent and have a high spin electron configuration of $d^5$, which has a vanishing orbital momentum. In the substituted materials Sr$_{1-x}$La$_x$Fe$_{12-x}$Co$_x$O$_{19}$, a fraction of Fe$^{3+}$ is substituted by Co$^{2+}$, and the same amount of Sr$^{2+}$ is substituted by La$^{3+}$ for charge compensation. The improvement of magnetic properties in this system is reported to be caused by drastic increment of the magnetocrystalline anisotropy field.$^5$ The origin of the enhancement of magnetocrystalline anisotropy field is thought to be due to not La$^{3+}$ but to Co$^{2+}$, which has a residual orbital momentum. However, in spite of many studies on La and Co substituted samples, the details remain unclear.

The crystal structure of M-type hexaferrite is regarded as alternate stacking of S-layers and R-layers,$^6$ and have crystallographically inequivalent five Fe sites, which include tetrahedral, octahedral, and trigonal-bipyramid sites. This complicated crystal structure make it difficult to determine the site where Co substituted.$^7,10$ In addition, almost all the previous studies of these substances were conducted using polycrystalline samples, and their results include the effect of orientations, grain size and grain boundaries. To remove these extrinsic effects, it is required to study using single crystals, though there are only a few reports dealing with single crystal growth.$^{11,13}$

In this paper, we report crystal growth, compositional analysis, and magnetic properties of single crystals of Sr$_{1-x}$La$_x$Fe$_{12-x}$Co$_x$O$_{19}$, and discuss the origin of the enhancement of magnetocrystalline anisotropy in this system. In our single crystals, content of La is greater than or equal to that of Co, indicating presence of Fe$^{2+}$. We measured saturation magnetizations and anisotropy fields, both of which increase with substitution content at 300 K. In addition, magnetocrystalline anisotropy energy is analyzed as a function of the contents of Co$^{2+}$ and Fe$^{2+}$ to elucidate the origin of magnetocrystalline anisotropy.

II. EXPERIMENTS

The single crystal samples of La and Co substituted strontium hexaferrites were grown using travelling solvent floating zone (TSFZ) technique in an infrared radiation furnace equipped with two ellipsoidal mirrors (SC-E15HD, Canon machinery). Stoichiometric mixtures of SrCO$_3$, LaFeO$_3$, Fe$_2$O$_3$ and CoO, were pressed into cylindrical rods, and these rods were sintered. As fluxes, mixtures of above materials were used. Typical chemical composition of these fluxed are (La,Sr)(Fe,Co)$_2$O$_4$. Crystals were grown at a rate of 1 mm/h under a 10 atm O$_2$ atmosphere. The typical size of the obtained single crystals is 4 mm in diameter and 60 mm in length. Powder x-ray diffraction measurements were conducted using a diffractometer with a Cu-Kα source (Miniflex600, Rigaku). We carried out compositional analysis of the single crystals using scanning electron microscopy/wavelength dispersive X-ray (SEM-WDX) analysis (INCA wave 500, Oxford Instruments, attached to SEM S-3500H, Hitachi) and inductively coupled plasma atomic emission spectrometry (ICP-AES) (JY138KH, Horiba Ltd.). Magnetization
that the main impurity is a spinel compound. The formation of impurities indicates that the chemical composition of M-phases in the samples with $x \geq 0.5$ are different from nominal compositions.

For $x \leq 0.4$, we conducted ICP measurements, which give averaged chemical compositions of bulk crystals. In order to determine chemical composition of M-phase in a sample that contains impurities, we have to remove the contribution of impurities, which are scattered in the crystals. For this purpose, we carried out SEM-WDX analysis of M-phases on cleaved surfaces of the sample with $0.1 \leq x \leq 0.7$. These results are summarized in figure 1. For $x \leq 0.4$, the results of both WDX and ICP are in good agreement with nominal compositions. However, for $x \geq 0.5$, Co contents obtained using WDX are obviously less than those of nominal compositions, though La contents are almost the same as those of nominal compositions. These results suggest that Co-substitution is limited to $x \leq 0.4$ under the condition that we applied. This value of substitution limit $x = 0.4$ is almost the same as previous report on polycrystalline samples synthesized in air, which may be a coincidence. For the sample with $x = 0.4$, equilibrium $O_2$ partial pressure is thought to be approximately 20% at 1200°C, the synthesis temperature of the polycrystalline sample. The single crystal with the same composition was grown at temperatures much higher than 1200°C, and equilibrium $O_2$ partial pressure becomes as high as 10 atm in this condition.

Our compositional analyses revealed that Co content is less than La content for $x \geq 0.5$. Then, the chemical formula is expressed as $\text{Sr}_{1-x} \text{La}_x \text{Fe}_{12-y} \text{Co}_y \text{O}_{19}$. Suppose it has no defect, one formula unit contains $y \text{Co}^{3+}$ and $(x - y) \text{Fe}^{2+}$ in addition to $(12 - x) \text{Fe}^{3+}$. In order to obtain single crystals for $x \geq 0.5$, we grew single crystals that have the limited Co content of $y = 0.4$. In these compositions, we succeeded in growing single crystals. One of the cleaved surface is displayed in the right inset of figure 1, clean surface of which indicates the absence of impurities. Chemical analysis using ICP shows that the La and Co contents of these single crystals are almost the same as the nominal compositions as shown in figure 1.

As mentioned above, we succeeded in obtaining single crystals of $\text{Sr}_{1-x} \text{La}_x \text{Fe}_{12-y} \text{Co}_y \text{O}_{19}$ where $y = x$ for $x \leq 0.4$, and $y = 0.4$ for $x \geq 0.4$, under a 10 atm $O_2$ atmosphere. These single crystals, which have a variety of chemical compositions, exhibit systematic variation of the Curie temperature $T_C$ as shown in the upper panel of figure 2, which indicates the success of single crystal growth that have a variety of chemical compositions. Although $T_C$ monotonically decreases with $x$, the slope of the $T_C - x$ curve differs below and above $x = 0.4$. For $x \leq 0.4$, $T_C$ is suppressed by both La and Co substitution with the slope of $dT_C/dx \approx -77.4 \text{K}$, which is consistent with previous study. For $x \geq 0.4$, $T_C$ is suppressed by additional La substitution, and the slope is $dT_C/dx \approx -33.7 \text{K}$. The suppression of $T_C$ in La and Co
substituted samples with \( x \leq 0.4 \) is due to the reduction of exchange coupling in the network of magnetic ions, where a fraction of \( \text{Fe}^{3+} \) ions is replaced by \( \text{Co}^{2+} \) ions. Similarly, the suppression of \( T_C \) for \( x \geq 0.4 \) is caused by the replacement of \( \text{Fe}^{3+} \) with \( \text{Fe}^{2+} \), the effect of which is suggested to be less than that of \( \text{Co}^{2+} \). Another possible origin of the difference of the slope is that the substituted site depends on the amount of substitution.

Systematic variations are observed also in the lattice constants of the hexagonal unit cell. The variations of the lattice constants \( a \) and \( c \); and the unit cell volume \( V \) are obtained by using powder x-ray diffraction as shown in the center and lower panels of figure 2, which is consistent with previous study on powder samples.\(^{17}\) As is different from \( T_C \), we observed no difference between the slopes of curves below and above \( x = 0.4 \). This fact suggests that the difference between \( \text{Co}^{2+} \) and \( \text{Fe}^{2+} \) gives little influence. The value of \( a \) slightly increases with \( x \), which is considered to be due to larger ionic radius of \( \text{Co}^{2+} \) and \( \text{Fe}^{2+} \) than that of \( \text{Fe}^{3+} \). The difference of the ionic radiuses is approximately 0.1 Å. At \( x = 1 \), the increment of \( a \) reaches approximately 0.005 Å, which is 0.12% of \( a \) at \( x = 0 \). This increment is approximately one twentieth of the difference of the ionic radius. In contrast, the value of \( c \) substantially decreases with \( x \), and the reduction of \( c \) at \( x = 1 \) is approximately 0.12 Å, which is 0.48% of \( c \) at \( x = 0 \). The decrement of \( c \) with \( x \) is mainly governed by La, which has a smaller ionic radius than that of Sr. These ions are coordinated by 12 oxygen atoms, and the difference of ionic radius with 12 coordination number is 0.08 Å.\(^{18}\) Although one unit cell includes two La layers, the decrement of \( c \) is limited to one and half times as large as the difference of ionic radius. As a result of the variations of \( a \) and \( c \), \( V \propto a^2c \) decreases with \( x \), and \( V \) at \( x = 1 \) is less than that at \( x = 0 \) by approximately 0.25%. If we ignore the difference of magnetization, this decrement of the volume enhances volume magnetization, which is preferable for permanent magnets.

Using these single crystals, we conducted systematic studies of magnetic properties. By applying magnetic field \( H \) parallel to the \( c \)-axis, which is easy-axis, \( M \) easily saturates approximately at 0.1 T.\(^{13}\) Thus, saturation magnetizations \( M_s \) were obtained as shown in figure 3. Owing to the limit of the maximum range of the magnetometer we used, we have to use small single crystals, typical mass of which is several mg. The experimental errors are evaluated to be approximately 1%, which are mainly due to both resolution limit of the electric balance and positional dependence of sensitivity of the magnetometer. In spite of a margin of errors, systematic variation is clearly observed. At 5 K, \( M_s \) increases with \( x \) for \( x \leq 0.4 \) and decreases for \( x \geq 0.4 \). This result suggests difference between the sites occupied by \( \text{Co}^{2+} \) for \( x \leq 0.4 \) and \( \text{Fe}^{2+} \) for \( x \geq 0.4 \). At \( x = 0 \), all the Fe ions are trivalent, having a \( d^5 \) electron configuration and

**FIG. 2.** The variations of \( T_C \), the lattice constants and the unit cell volume of \( \text{Sr}_{1-x}\text{La}_x\text{Fe}_{12-y}\text{Co}_y\text{O}_{19} \) as a function of La content \( x \). In the region of \( x \leq 0.4 \), Co content \( y \) is equal to \( x \). For \( x \geq 0.4 \), we fix \( y = 0.4 \). The lines in the graphs are the results of linear fittings.

**FIG. 3.** The variation of saturation magnetization \( M_s \) per formula unit as a function of La content \( x \). As is the same as before, Co content \( y \) is equal to \( x \) for \( x \leq 0.4 \), and we fix \( y = 0.4 \) for \( x \geq 0.4 \). Upper and lower panels are the results measured at 5 K and 300 K, respectively. The filled circles indicate the measured value and the bars scale experimental errors. The lines are eyeguide. The inset shows, temperature dependence of \( M_s \) for \( x = 0, 0.4, 1 \), which was measured at 1 T for \( H \parallel c \).
magnetic moment of $5 \mu_B$. While Co$^{2+}$ has an electron configuration of $d^7$ and magnetic moment of $3 \mu_B$. Suppose all the Co$^{2+}$ occupy minority spin sites, increment of $M_s$ at $x = 0.4$ should be $0.8 \mu_B$. The observed increment is approximately half, which means that three fourth of Co$^{2+}$ ions occupy minority spin sites, and the rest of them occupy majority spin sites. Our results is consistent with previous Mössbauer studies$^{7,8,19}$ that suggest Co$^{2+}$ occupies $4a$ (majority spin) site and $4f_2$ (minority spin) site, and NMR study$^9$ that suggests it occupies $4f_1$ (minority spin) or $4f_2$ sites. The difference between $M_s$ at $x = 0.4$ and $x = 1$ is in good agreement with the value 0.6 $\mu_B$ calculated based on the assumption that all the Fe$^{2+}$ ions with $4 \mu_B$ occupy majority spin sites.

As is different from $M_s$ at 5 K, $M_s$ increases monotonically with $x$ at 300 K, although the slope of $M_s$-x curve changes at $x = 0.4$. This difference arise from the temperature dependence of $M_s$. As shown in the inset of figure 3, $M_s$ at $x = 1$ decreases slower than those at $x = 0.4$ with increasing temperature. As a result, $M_s$ at room temperature has the largest value at $x = 1$. The mean field theory of ferrimagnets suggests that magnetization of small spin quantum number has smaller temperature dependence than that of large spin quantum number below $T_C$. Hence, considering that Fe$^{2+}$ is placed in majority spin sites, thermal demagnetization would be suppressed by the substitution of Fe$^{3+}$ with Fe$^{2+}$, which has smaller spin quantum number. Our experimental result is in good agreement with this explanation. While, $M_s$ at $x = 0$ and 0.4 have almost the same temperature dependence. The effect of small spin for the $x = 0.4$ sample is seemingly cancelled, since Co$^{2+}$ distributed to both majority and minority spin sites.

In addition to saturation magnetization, magnetic anisotropy is one of the most important properties as materials for permanent magnet. Using single crystals, we can examine magnetic anisotropy in detail. If magnetic field is applied along the $c$-axis of a single crystal, $M$ steeply increases up to $M_s$ owing to the strong easy axis magnetic anisotropy. This property was used in order to measure $M_u$. In contrast, if magnetic field is applied perpendicular to the $c$-axis of a single crystal, $M$ gradually increases. In this case, the slope of the $M$-$\mu_0H$ curve provides a measure of magnetic anisotropy.

The $M$-$\mu_0H$ curves measured under $H$ perpendicular to the $c$-axis, are displayed in figure 4. At 300 K, all the $M$-$\mu_0H$ curves are almost linear up to $M_u$, and show saturated behavior after that. The initial slope decreases with $x$, indicating increment of magnetic anisotropy both below and above $x = 0.4$. Similarly, the initial slope of $M$-$\mu_0H$ curve measured at 5 K, seems to decrease with $x$. However, $M$-$\mu_0H$ curves measured at 5 K is qualitatively different from those at 300 K. Only for SrFe$_{12}$O$_{16}$ ($x = 0$), the curve is linear up to $M_s$ as is the same as those at 300 K. For $x \geq 0.1$, $M$ linearly increases with $\mu_0H$ up to approximately 80% of $M_s$, and the slope gradually decreases. For largely substituted samples, $M$ does not saturate even at 7 T, which is the highest field we applied.

The decrement of the slope is possibly due to the effect of Co$^{2+}$ or Fe$^{2+}$, which will be discussed later.

The value of $H$ at which $M$ reaches $M_u$ is called anisotropy field $H_A$, which is a measure of magnetocrystalline anisotropy. At 300 K, each magnetization curve has a singular point. By using singular point detection technique, $H_A$ is defined as the value of $H$ at the singular point, which is denoted as $H_{SPD}$ here. At 300 K, the values of $\mu_0H_{SPD}$ can be easily evaluated from $M$-$\mu_0H$ curves in the lower panel of figure 4. However, this technique does not work well at 5 K, since some of the magnetization curves at 5 K have no singular point. If a $M$-$\mu_0H$ curve is a straight line up to $M_u$, $H_A$ is expressed as $\mu_0H_A = M_u/\chi_\perp$, where $\chi_\perp$ is $M/\mu_0H$ under weak $H$ that is applied perpendicular to the $c$-axis. Here, we define $H_A$ as $\mu_0H_A = M_u/\chi_\perp(0.1T)$. Although, the values of $H_A$ at 300 K are slightly lower than those of $H_{SPD}$, $H_A$ can be measured in all temperature range by using this definition.

In order to obtain temperature dependence of $H_A$, we measured temperature dependence of $M$ under 0.1 T that is applied perpendicular to the $c$-axis. As shown in the inset of figure 4, $\chi_\perp$ of the sample at $x = 0$ monotonically decreases with increasing temperature, the behavior...
of which is very similar to that of $M_a$ in the inset of figure 3. In contrast, $\chi_\perp$ of the sample at $x = 1$ slightly increases with temperature. Using $\chi_\perp(T)$ under 0.1 T and $M_a(T)$, we calculated $\mu_0 H_A$ as a function of temperature, the result of which is shown in the inset of figure 5. At $x = 0$, $\mu_0 H_A$ ($\simeq \mu_0 H_{\text{SPD}}$) is approximately equal to 1.8 T, which is almost independent of temperature. This value of $H_A$ is consistent with previous report.\textsuperscript{21} With increasing $x$, $H_A$ is highly enhanced at low temperatures. It reaches 4.2 T for the $x = 1$ sample at 5 K. However, $H_A$ of high $x$ samples substantially decreases with increasing temperature. At 300 K, $\mu_0 H_A$ of the $x = 1$ sample is limited to 2.8 T, and $\mu_0 H_{\text{SPD}}$ is approximately 3.0 T. Although this value is the highest value among previously reported M-type ferrites at room temperature, it is much lower than that at 5 K. The enhancement of $H_{\text{SPD}}$

for $x \leq 0.4$\textsuperscript{19,21} and temperature dependence of $H_{\text{SPD}}$ above 150 K\textsuperscript{21,22} were already reported. Although $H_A$ is slightly higher than $H_{\text{SPD}}$ owing to the difference of definition, our results are consistent with previous reports. In contrast, the enhancement for $x \geq 0.4$ indicates that Fe\textsuperscript{2+} also enhances the magnetic anisotropy. Although the enhancement of $H_A$ was reported for LaFe\textsubscript{12}O\textsubscript{19} at low temperature\textsuperscript{23}, the enhancement for $x > 0.4$ at room temperature has not been reported before and discovered for the first time. Please recall that the Co content is fixed to 0.4 for $x \geq 0.4$.

To elucidate the origin of enhancement of $H_A$ and gradual decrement of the slopes of $M - \mu_0 H$ curves at 5 K, we evaluated magnetocrystalline anisotropy energy $E_a$. Using a $M - \mu_0 H$ curve under $H$ perpendicular to the $c$-axis, $E_a$ can be obtained by

$$E_a(\theta) = \int_0^{\mu_0 H d M} \mu_0 H d M,$$

where $\theta$ is the angle between the $c$-axis and the magnetization vector, namely, $\sin \theta = M/M_a$. If a $M - \mu_0 H$ curve is a straight line and $M$ saturates at $\mu_0 H = \mu_0 H_A$, $E_a$ is expressed as $K_{u1} \sin^2 \theta$, where $K_{u1} = \frac{1}{2} H_A M_a$ is the first uniaxial anisotropy constant. However, most of $M - \mu_0 H$ curves measured at 5 K is not linear, indicating that $E_a$ is not expressed using above formula. In figure 5, $E_a$ at 5 K for the $x = y = 0.4$ sample is plotted as a function of $\sin^2 \theta$. The $E_a \sin^2 \theta$ curve is not linear, rather it is concave upward. We tried to fit this curve using the formula that includes higher order terms\textsuperscript{24},

$$E_a(\theta) = K_{u1} \sin^2 \theta + K_{u2} \sin^4 \theta + \cdots.$$ 

The curve using $K_{u1}$ and $K_{u2}$ is plotted in figure 5 as an example. Although the result is better than that using a line, it does not reproduce the rapid increase of experimentally obtained $E_a$ around $\sin^2 \theta = 1$. In order to reproduce it, very high order terms are required. The introduction of very high order term is not reasonable.

It was proposed that uniaxial magnetocrystalline anisotropy is enhanced by single ion anisotropy of Co\textsuperscript{2+25}, which originates in spin-orbit interaction. The energy of spin-orbit interaction is given by $\lambda L \cdot S$, where $\lambda$ is the spin-orbit coupling constant, and $L$ is the non-vanishing orbital momentum. The direction of $L$ is governed by crystal field, which depends on the sites. In the hexagonal M-type ferrite, the sum of $L$ is considered to be parallel to the six fold axis, namely, the $c$-axis. Hence, we suppose $\lambda L \cdot S \propto \cos \theta$. In order to fit the $E_a$ data, we used a formula including spin-orbit interaction,

$$E_a(\theta) = C_1 (1 - \cos \theta) + C_2 \sin^2 \theta,$$

where $C_1$ and $C_2$ are coefficients. The result of the fitting for the $x = y = 0.4$ sample is plotted in figure 5. Compared with the previous fitting, it well reproduce the data in all $\theta$ region, indicating that this formula is useful in this system.
In figure 6, obtained µ of Co is proportional to the content of spin-orbit interaction, is proportional to the content for x = 0.4, y = 0.4 for x ≥ 0.4], and investigated their magnetic properties. With increasing x, the unit cell volume decreases, and both saturation magnetization and anisotropy field monotonically increase. We conclude that LaFe_{11.0}Co_{0.4}O_{12} is the best candidate that could have high maximum energy product in hexaferrites. Especially, by using the directly measured magnetic anisotropy of single crystals, we established a proper analysis method to characterize their microscopic origins. This analysis gives strong evidence that the enhancement of anisotropy field for x ≤ 0.4 originates in the spin-orbit coupling of substituted Co^{2+} ions. Moreover, we found for the first time that single ion anisotropy of Fe^{2+} also enhances anisotropy field for x ≥ 0.4 at room temperature. In this work, LaFe_{11.0}Co_{0.4}O_{12} was prepared with the new idea that the same amount substitution of La and Co is not necessary for Sr_{1−x}La_{x}Fe_{12−y}Co_{y}O_{19} system, and that the produced Fe^{2+} further enhances magnetic properties. Our result indicate possibility of developing a high \( H_A \) hexaferrite without Co utilizing the enhancement of \( H_A \) by Fe^{2+}.

IV. CONCLUSIONS

In this work, we successfully grew single crystals of hexaferrites \( \text{Sr}_{1-x}\text{La}_{x}\text{Fe}_{12-y}\text{Co}_{y}\text{O}_{19} \) (x = y for x ≤ 0.4, y = 0.4 for x ≥ 0.4), and investigated their magnetic properties. With increasing x, the unit cell volume decreases, and both saturation magnetization and anisotropy field monotonically increase. We conclude that LaFe_{11.0}Co_{0.4}O_{12} is the best candidate that could have high maximum energy product in hexaferrites. Especially, by using the directly measured magnetic anisotropy of single crystals, we established a proper analysis method to characterize their microscopic origins. This analysis gives strong evidence that the enhancement of anisotropy field for x ≤ 0.4 originates in the spin-orbit coupling of substituted Co^{2+} ions. Moreover, we found for the first time that single ion anisotropy of Fe^{2+} also enhances anisotropy field for x ≥ 0.4 at room temperature. In this work, LaFe_{11.0}Co_{0.4}O_{12} was prepared with the new idea that the same amount substitution of La and Co is not necessary for Sr_{1−x}La_{x}Fe_{12−y}Co_{y}O_{19} system, and that the produced Fe^{2+} further enhances magnetic properties. Our result indicate possibility of developing a high \( H_A \) hexaferrite without Co utilizing the enhancement of \( H_A \) by Fe^{2+}.
