Abstract

Recently it was demonstrated that atomic oxygen can cause the extraction of substrate atoms off metal surfaces thus generating chemically different active sites. For Ag(110) this process occurs when O₂ is dosed at 175 K leading, at low coverage, to the formation of single Ag vacancies. Vacancy creation proceeds thereby via the formation of O-Ag-O complexes, which involve a local reconstruction of the surface and ignite the disruption of the Ag substrate. In this paper, we report on the details of such processes and on the isolated structures formed by the O adatoms in the limit of very low coverage. We employ scanning tunnelling microscopy and density functional theory to unravel the complex structures of O/Ag(110) which are transiently present under specific reaction conditions. A variety of features such as isolated grey dots, sombreros, shallow grey and white structures oriented along [001] and [110], grey stripes, and lozenges were identified and assigned to O adatoms in different configurations. The zig-zag chains interact strongly with the STM tip and are easily disrupted, giving rise to highly mobile, sombrero shaped, isolated O adatoms also far away from the scanned area, i.e. from the current injection spot. Around 200 K, not only Ag vacancies, which are mobile with anisotropic migration, can merge together into rather complex features, but also the mobile Ag atoms are trapped by O adatoms, thus facilitating the formation of an oxygen-decorated Ag chain along [001] which ultimately induces the well-known added row reconstruction.
I. INTRODUCTION

Silver is a unique material, used for catalysing industrially relevant reactions such as dehydrogenation of methanol [1], partial oxidation of ethylene [2-4], and oxidation of formaldehyde [5,6] and propylene [7,8]. The importance of silver in influencing these reactions has inspired researchers to put significant efforts in gaining insights into the chemical activity of surface structures of O/Ag systems. For example, the active O species responsible for ethylene oxide formation on Ag(111) [9,10] were recently identified, but the mitigating processes are still far from being fully understood [11,12]. One obstacle in the advancement of knowledge about the reactivity of the Ag catalyst in an oxidative environment is the complexity of the O-Ag system: the intricacy of the structures often involves the adsorption configurations of O species, inducing substrate reconstruction [13], oxygen migration to the Ag subsurface region [10,14], and formation of surface oxide phases [15].

Molecular oxygen adsorbs dissociatively on low Miller index Ag surfaces at crystal temperatures T>150 K [16-19]. On the anisotropic Ag(110) face, in particular, substrate atom mobility sets in only at T=200 K, leading to the formation of the well-known added row reconstruction, consisting of -O-Ag-O-Ag- chains extending along the [001] direction [20,21] (i.e. across the atomic rows of the substrate - see surface geometry in Fig. 1A). On the same surface, for 150 K<T<200 K, dissociative O2 adsorption can lead to the formation of an O species with a higher chemical activity than both O2 admolecules and O adatoms that are embedded in the added rows [22]. In the low coverage limit, indeed, different isolated features corresponding to the different O species are revealed by Scanning Tunnelling Microscopy (STM) investigation [23-25]. We have recently demonstrated that shallow stripes extending in the [1\bar{1}0] direction (apparent depth from 0.1 Å to 0.5 Å) – referred to as grey stripes in the following and marked in Fig. 1(B) – are related to structures containing several O adatoms in a zig-zag configuration. A deeper feature (0.7 – 1.0 Å deep, depending on measuring conditions – black dot (BD) in the following – marked in Fig. 1B) results from vacancies induced by dissociative adsorption of oxygen on Ag(110) [26]. These results clarified several unexplained observations such as the strong disordering of the surface upon O2 dissociation [16] and the facile route by which oxygen migrates to subsurface sites even at low temperature [27]. Along the same lines, it is also likely that the strong reduction of the barrier for metalation of porphyrins on Cu surfaces in the presence of coadsorbed oxygen [28,29] is associated with the grabbing of substrate atoms by atomic oxygen. As stressed in ref. [26], these effects are not limited to Ag and Cu substrates, but are expected to occur for a wide category of metal substrates.
Nonetheless, a variety of O-related structures other than the two reported in ref. [26] is observed on the O/Ag(110) surface upon O₂ dissociation. Here, we provide a complete and detailed description of the structures formed on Ag(110) in the very low atomic oxygen coverage limit (Θ<0.04 ML) based on low-temperature high-resolution STM images and density functional theory (DFT) based simulations. The paper is organized as follows: we describe the experimental and computational details in section 2, we present our results from experiment and DFT simulation in section 3 and section 4, respectively, and we summarize our findings in section 5.

II. EXPERIMENTAL AND COMPUTATIONAL METHODS

The Low Temperature STM (LT-STM, CreaTec) employed to perform the present experiments is hosted in an ultra-high vacuum apparatus thoroughly described in ref. [30]. O₂ dosing was performed by backfilling the chamber. The attained coverage was evaluated \textit{a posteriori}, by statistical analysis of large STM overviews. The estimated value is compatible within the error with the one expected, \textit{a priori}, considering an O₂ sticking coefficient S~ 2x10⁻³, according to previous literature [31,32].

The Ag(110) single crystal was prepared by repeated cycles of ion bombardment with 1.5 keV Ne⁺ ions and annealing to 800 K for 5 minutes, until clean large terraces were observed by STM. STM images were recorded either at liquid nitrogen or at liquid helium temperature, using constant current mode and tunnelling current between 0.5 nA<I< 2.0 nA. The bias voltage applied to the sample was varied between -1.20 V≤V≤1.20 V. Scanning at |V|=0.56 V resulted in surface disruption also far away from scanned area as we will show later. Most of the images were therefore recorded for V=±0.07 V and ~1 nA, which corresponds to a charge injection of some 6×10⁸ electrons per surface unit cell. At such low voltage, local manipulation of the oxygen atoms could be achieved with a roughly 3 order of magnitude larger charge injection.

The STM tip is a Pt-Ir wire of 0.2 mm diameter, cut in air under strain. During the measurements, the tip apex is reshaped by controlled crashes into the Ag sample, so that tunnelling occurs effectively through a silver tip. The piezo constants were calibrated on the basis of the Ag lattice parameter from atomically resolved images of the clean surface. The interplay of the various electronic effects can change the contrast of STM images as demonstrated e.g. in ref. [33,34]. Indeed we observed such effect occasionally but the modification was not stable enough to allow collecting images over large areas. The conclusions of the present investigation are, therefore, limited to the analysis of data recorded with a metallic tip. Analysis of the images was performed using both the acquisition software supplied by Createc and the WSxM software [35].
Density functional theory (DFT) calculations were performed using the Vienna ab-initio Simulation Package (VASP) [36,37]. The exchange-correlation of electrons was treated within the generalised-gradient approximation with the PBE [38] functional. The projector-augmented-wave method [39] was adopted to account for the ion-electron interaction. Periodic (3x4), (4x4) and (6x8) supercells of Ag(110) were constructed using the calculated bulk lattice constant of 4.147 Å and setting the vacuum of 15 Å. The energy cutoff was set to 500 eV for the plane-wave expansion. All atoms were allowed to relax freely including the adsorbates until the total energy is converged to 10^-5 eV, and the residual force on each atom is below 0.01 eV/Å. For the relaxation of the geometries of the (3x4), (4x4), and (6x8) unit cells, (7x7x1), (6x7x1), and (4x4x1) k-points meshes, and for the simulation of STM images, (21x21x1), (18x21x1) and (9x9x1) k-points meshes were employed, respectively.

The binding energy for oxygen per O atom adsorbed on Ag(110) is calculated using

$$E_{b}^{0\text{-adatom}} = \frac{1}{n}[E_{nO/Ag(110)} - (nE_{O} + E_{Ag(110)})],$$

where n represents the number of O adatoms per surface unit cell, and E_O, E_{Ag(110)} and E_{O/Ag(110)} represent the total energies of the isolated O atom, the pristine surface, and the adsorbate-substrate system, respectively. Based on this expression, the adsorbed oxygen that has a negative value of binding energy is stable. Note that this expression has different sign convention from that found in an earlier study [40] for calculating the same quantity on Ag(111). Similar to the procedure adopted in ref. [40], spin-polarization corrections to the isolated, free atomic oxygen were included in total energy calculations.

The Tersoff and Hamann (TH) model [41] was applied to simulate STM images at low bias voltage, V. At higher V, the simulated STM images were approximated by the DFT-calculated iso-surface (with iso-value of 10^-4 e/Å^3) of the local density of states (DOS) integrated over the sample states from -V (in eV) to the Fermi level.

III. RESULTS AND DISCUSSION

A. Experimental STM
Fig. 1. A) Geometry of the Ag(110) surface. The four-fold hollow (FFH), long bridge (LB), short bridge (SB) and three-fold hollow (TFH) sites, relevant for the data presentation are marked on the left part of the drawing. The structure of the Ag(110)-O-(2x1) added row reconstruction is shown in the right part. B) STM image of the Ag(110) surface exposed to 19 L of O₂ at 175 K (image size: 25x25 nm², V=0.07 V, I=1.3 nA, virgin area). Black dot (BD) decorated by grey stripes, isolated grey dot (Gd), lozenge (L), added row (AD), grey and white dot oriented along [100] (GW) and isolated cluster structures are apparent on the terraces. The dashed box indicates the area subject to the manipulation experiment reported in Fig. 4. Added rows stretch along the [001] direction while G stripes have the axis aligned along [1 0].

Fig. 1B shows an area of the Ag(110) surface after exposure to 19 L of O₂ at 175 K and cooling to 6 K. The atomic oxygen coverage estimated from STM images is ~0.02 ML (in monolayers of Ag(110); 1 ML corresponding to 8.4 × 10¹⁴ atoms/cm²). A variety of O-related features is evident on the surface: i) 0.8 Å deep BD with 0.4 Å deep grey stripes. The latters sometimes appear as isolated grey dots (Gd); ii) 0.2 Å deep lozenge shaped structures (L); iii) grey and white couples oriented along [001] (GW[001]); iv) few additional protruding objects (cluster). The initial formation of added -O-Ag-O-Ag- rows is evident at the lower side of steps. These added rows originate from Ag atoms released from the step edges and are imaged with atomic resolution. As demonstrated in our previous publication [26], G stripes correspond to zig-zag rows of oxygen adatoms in three-fold hollow sites while BD are single vacancies produced by adatom extraction. The other structures will be described in the following.
Before providing the details of the observed structures, it is necessary to point to some ambiguities, which have prevented a full understanding of the O/Ag(110) system so far. The STM investigation of the system is indeed extremely delicate since scanning above a critical bias voltage (|V|≥0.7 V) destroys the surface layer. This effect, first reported in ref. [26], is particularly pernicious, since it is evident only in images recorded close to liquid helium temperature (6 K) and at low V. It was therefore not discerned in previous investigations [23,24]. In the following we will mainly concentrate on measurements recorded at ±0.07 and ±0.70 V sample bias.

Fig. 2 shows STM images recorded after the same preparation as in Fig. 1 and evidencing the effect of tip-surface interaction. Panel A1 shows a virgin area (i.e. not yet scanned by the STM tip) in which several different features, including BDs and grey stripes are present. A voltage pulse with V=1.0 V is eventually applied on the vacancy site marked by the yellow dot in the enlarged panel A2 and the whole area is imaged again (panel A3). It is evident that the stripes have now disappeared while the BDs are unaffected. The surface is now covered by sombrero-shaped objects (S) corresponding to single O adatoms. This assignment is demonstrated by our recent publication [26] and by a previous experiment by Hahn and Ho [42-44], who produced very similar features by disrupting chemisorbed O₂ admolecules by voltage pulses at 13 K. No sombreros are present on virgin areas, i.e. prior to the vertical manipulation process, implying that they are unstable as isolated features when dissociation occurs at 175 K.
Fig. 2. Overviews showing the disruption of the surface upon interaction with the tip above a critical bias voltage. A) STM images of the same region before (A1) and after (A3) applying a voltage ramp (from 0 to V=1.0 V for a total of 600 ms with the tip retracted by 1 Å with respect to its position when acquiring images) on the vacancy site marked with the yellow dot in the enlarged panel A2 (corresponding to the area in the dashed square in A1). V=0.07 V, I=1.3 nA, image size: 34x30 nm² for A1 and A3, 7.0x7.0 nm² for A2. The fuzzy appearance of the image in A3 may be associated with the functionalization of the tip, most probably from the adsorption of an oxygen atom. Disorder over a wide area is however evident. B) Sequence of STM images showing the consequences of scanning above a critical voltage on small areas (yellow dashed square, 5.0x5.0 nm²): B1) before scanning; B2) after scanning the marked area in B1 with a maximum voltage V=0.20 V, 1.0 nA. No changes in the surface morphology are observed. B3) after scanning the marked area in B2 with a maximum voltage V=±0.56 V. The damage is now evident and extends over an area much larger than the scanned one.

The sequence of STM images reported in B panels shows the consequences of scanning above a critical voltage on a small area (marked by the yellow dashed squares). As evident, no changes in the surface morphology are induced upon interaction with the tip at V=0.20 V (panel B2), while rastering the small region in the top-left corner with V=±0.56 V causes a disordering of the adsorbed layer which extends over a much larger area (panel B3). Sombreros are found up to 40 nm away from the scanned region, indicating that their formation is a surface-mediated phenomenon. A similar effect was reported by Hahn et al. [45] or tip current induced dissociation of O₂ chemisorbed on Ag(110) at 13 K, but it was unexpected in the present case since the initial state consists of already dissociated oxygen.

Fig. 3 shows a similar experiment, in which subsequent STM images of the same surface area were recorded at different bias voltages and at liquid nitrogen temperature (77 K). While the position of O-related structures remains unchanged through the sequence, short stripes in the scanning direction are evident in the images at V=±0.07 V. We interpret them as due to sombrero features rapidly moving below the tip, i.e. too mobile to be imaged at liquid N₂ temperature. Similar stripes were observed in refs. [23,24] (in images recorded at 110 K) and assigned to O₂ admolecules. As it is improbable that admolecules survive annealing to 175 K, such possibility is excluded in our experiment, since oxygen exposure was performed directly at 175 K and the sample remained at that temperature for a prolonged time. In the same publications, sombrero-shaped objects were also observed but left unassigned. However, such features must be qualitatively
different from the present ones, since they can be clearly imaged at $T=110$ K with a typical bias voltage of $1$ V.

Fig. 3. Sequence of STM images of the Ag(110) surface exposed to 18 L of O$_2$ at 180 K recorded at different $V$ ($I=1.0$ nA, image size: 22.5x22.5 nm$^2$) and at $T=77$ K. At low bias voltage (panels B and C) short stripes are present in the scanning direction (horizontal) due to the movement of weakly bonded oxygen adatoms under the tip while the image is recorded. Such effect is absent in the images collected at $V=\pm0.7$ V (panels A and D) since the apparent depth of sombreros is then smaller (see Fig. 8 below).

To better characterize the behavior of the above described features we performed manipulation experiments reported in Fig. 4, starting from the surface area marked by the yellow box in Fig. 1. Column A refers to manipulation over a BD and the associated grey stripe. Upon vertical manipulation on a BD (yellow mark on panel A1), i.e. by applying a voltage pulse with $V=+0.07$ V and 1 nA for 200 msec (corresponding to roughly three orders of magnitude larger electron dose per unit cell than when collecting an image by rastering), the grey tail is shortened by two lattice spacings [26] and two sombreros, initially absent from the surface, are generated (panel A2). The grey tail corresponds therefore to oxygen atoms. The second pulse, applied directly on the far left end of the grey tail, causes again the generation of two sombreros and the corresponding shortening of the tail by two lattice spacings, (panel A3). The procedure is repeated until only the BD remains. A secondary effect of the voltage pulses is to swap the white and the grey part of the GW structure marked by the arrow in panel A3.

The manipulation sequence of column B is performed on the same area to better characterize the behavior of sombreros. It shows that two sombreros can approach each other in a controlled way and merge to form a GW feature oriented along the [1 0] direction (see white arrow in panels B2-B4), which is reproduced by DFT as an O-Ag-O complex embedded in the Ag surface (see Fig. 10). While the protrusion remains fixed, the position of the depression can be swapped by further manipulation (compare panels B3 and B4), obtaining an object with a specular profile (line scans
GW1 and GW2). The GW feature generated by manipulation can be separated into its original components, as demonstrated by panels C1 and C2. In addition, the same images show that two sombreros can merge forming a GW oriented along the [001] direction (white arrow in panels C2 and C3). Finally, the isolated Gd in the bottom-left quarter of the image presents an apparent depth comparable to the GW structures but the additional side protrusion is missing (see line scans at the bottom of column B). Therefore, it must correspond to a different configuration of oxygen adatoms.
Fig. 4. STM images showing three manipulation sequences performed on different objects present in the same area. In sequence A sombreros are generated from the grey tail of a black dot by
voltage pulses. Two new sombreros form for each pulse. In sequence B sombreros merge into a GW [\bar{1}10] structure. In sequence C such structure is broken again into two sombreros (For all images: size: 12.1 x 12.1 nm², V=0.07 V, I=1.3 nA. Vertical manipulation parameters: 0.07 V, 1 nA, 200 msec applied to the positions marked by yellow dots). Schematic representations for the main processes are given, too. Left: The Grey tail (\textendash O-Ag-O-Ag-O- zig-zag chain) is shown by rectangular box. The shortening of the chain leads to two sombreros (isolated O adatoms at LB site), shown by circles. The continuous process shortening the tail gives rise to a black dot (isolated Ag vacancy), shown by dotted small circle. Bottom of column B: Merging two sombreros into an O-Ag-O complex, shown by oval. Bottom of column C: Breaking of a pair of O adatoms (involved in the complex) into the original sombreros. Bottom of the column: Apparent depth profiles cut in the [\bar{1}10] direction across the manipulated GW structure of panel B3 and B4 and across the pristine grey dot located at the bottom-left of the images. A more detailed description of the described events is reported in the Supplementary material.

In order to determine the relative positions of the observed features with respect to the underlying Ag(110) substrate, we exploited images as those of Fig. 5, in which the O-related structures coexist with isolated added rows (see scheme in Fig. 1A). The latter are imaged with atomic resolution and always terminate with a brighter spot, which corresponds to an Ag atom [47]. Since it is well-established that the Ag atoms in the added rows sit in the hollow sites (H) of the unreconstructed Ag(110) plane, we can use this structure as reference to draw a grid corresponding to the lattice of the unreconstructed Ag(110) plane underneath (Ag atoms are located in the intersections of the grid). From this construction, we can determine that BDs and grey stripes sit on top of the atomic rows of the Ag substrate (panels 5a and 5b). Lozenges, on the contrary, have their long axis in the valley and their centre in a H site, while sombreros are adsorbed at LB sites. The position of isolated grey dots is more difficult to determine. They seem to sit in on-top position, but more statistics on high resolution images would be needed for a careful assignment. Similarly, we are not able at the moment to identify the position of the GW[001] features with accuracy.
Fig. 5. STM images recorded after exposing the surface to 19 L O₂ by backfilling at 175 K. BD and G structures co-exist with the added O-Ag rows extending along the [001] direction. The yellow spots (black arrow) correspond to terminal Ag atoms of added rows, which are known to be at hollow sites. Taking these features as reference, a grid corresponding to the Ag lattice is superimposed to the image. Both BD and G structures are located on top of the Ag rows (panel a). The same procedure allows to locate the centre of the lozenges (L) at hollow sites (panel b) and sombreros (S) at long bridge sites (panel c). For all images, size: 100 x 100 Å², V=31 mV in a) and 0.07 V in (b-c). Bottom-left inset: color scale for the apparent height. Taken from the Supporting Information of ref. [26].

We observe that the two BDs in Fig. 5a appear slightly elongated along [1 0] and that their centre lies at a short bridge (SB) site. On the contrary, the BD in panel c, obtained by “cleaning” off its grey tails by voltage pulses as described in Fig. 4A, appears round and its centre coincides with an Ag lattice site. We conclude that BDs may correspond either to pairs of vacancies (elongated features) or to single vacancies (round BD). Thus, merging of vacancies takes place already at 175 K, implying that Ag atoms have some mobility already at this temperature. Short-range Ag atom mobility is not surprising and is witnessed also by the appearance of some short-added rows at the lower side of step edges.

Vacancies are efficient pinning centres for the grey stripes. We remark that also residual O₂ admolecules are imaged as 0.4 Å deep indentations [42-44], and that they would also release two oxygen atoms upon disruption. However, in our experimental conditions, the assignment of grey features (pristine dots and stripes) to atomic oxygen is straightforward since the presence of admolecules is ruled out by the dosing temperature, as discussed above.
Fig. 6. STM images showing lozenges recorded at different tip bias (I= 1.0 nA, T= 6 K, image size= 2.2 x 3.0 nm$^2$) and corresponding line profiles cut along the [1-10] direction, i.e. along the major axis of the lozenge. The distance between the center of the lobes in this direction is 7.5 Å.

Lozenges (L) appear as slight indentations with two lobes and are observed at any bias voltage in the investigated range (see Fig. 6). These features, more abundant in stepped areas, first appear at T>170 K and can be associated with some reconstructive geometry of O and Ag atoms [23], as it will be shown in Fig. 13.

Fig. 7 shows two additional features seldom observed upon the same preparation. As evident in the enlargement of panel B and from the line profiles of panel C, the former (1) appears as two half-lozenges at the opposite side of a protrusion, probably an Ag adatom trapped in between them. In case (2), the same structure is sided by grey dots. These structures correspond most probably to the “clusters” reported in ref. [24]. The latter feature (3) is a rectangular-shaped object reminiscent of four close-by grey dots. However, it was observed also in-between a (6x1) added row reconstructed surface produced by O$_2$ exposure at room temperature and can be imaged at V≥1.0 V [47]. In view of this particular behavior, we believe that it is probably an O-related feature but with a different nature with respect to grey dots.
Fig. 7. A) STM overview (25x25 nm², 70 mV) of the Ag(110) surface after exposure to 19 L of O₂ at 175 K. B) Enlargement of the area marked by the dashed yellow square in A) (6.0x6.0 nm², 1.3 nA, 70 mV). Images are recorded at 6 K. The additional cluster features discussed in the text are evident. C) Height profiles cut across the different O-related structures following the path marked by the corresponding dashed lines in B).

B. DFT and KMC Simulations

In order to unravel the objects observed experimentally, as in our previous joint publication [48], we have carried out density functional theory based calculations to obtain the following for various configurations of the O/Ag(110) system: relaxed (ionically) geometry, energetics and activation energy barriers of several relevant phenomena (adsorption, vacancy formation, diffusion), and simulated STM images. Note that these detailed results have not been reported in our earlier publication [48]. We discuss first the simulated STM images.

1. Simulated STM images

1.1 Isolated O adatoms

Fig. 8. (A1-A3) DFT-optimized geometries of O adatoms at A1) FFH A2) LB and A3) TFH sites; (B1-B3 and C1-C3) corresponding simulated STM images at B1-B3) V=70 mV and C1-C2) V=700
mV, C3 V=700 mV; (D1-D3) corresponding line profiles for V=70 mV (blue solid line), V=700 mV for C1 and C2 and 700 mV for C3 (dashed line) collected along [110] for D1 and D2 and along [001] for D3. The experimental data recorded at 70 mV are reported for comparison (green line) when available.

Fig. 8 shows the optimized geometries, the simulated STM images and the corresponding line profiles of O adatoms at four-fold hollow (FFH – panel A1), long-bridge (LB – panel A2), and three-fold hollow (TFH – panel A3) sites. The details of the geometrical parameters and adsorption energy of the O adatoms can be found in Ref. [48]. The simulated STM images at V=70 mV (column B) and 700 mV (column C) are compared with available experimental data (column D) as follows:

i) An O adatom at the FFH site (upper panel, Fig. 8) appears as a depression in the STM image with 0.4 Å depth in the profile simulated at V=70 mV and as a relatively shallow contrast at 700 mV, thus showing a good agreement with the line profile of the grey dots measured at V=70 mV (see the measured line profile in Fig. 4). At V=700 mV, however, as mentioned above this species is not stable under the STM tip, thus no experimental data is available to compare with the calculated one.

ii) O at the LB site appears as a sombrero-like object in the simulated STM image at 70 mV (see Fig. 8B2). It is characterized by two equivalent 0.25Å deep indentations on both sides of the O adatom as seen in the corresponding depth profile. Therefore, the experimentally observed S feature in Fig.5c can be safely assigned to such O/Ag configuration. At V= 700 mV, however, the calculated STM image shows a smaller contrast with shallow depth in the calculated profile (see Fig. 8C2, D2). The comparison of STM simulation for V=700 mV with experiment is also not possible since the S structures cannot be imaged at the corresponding measuring conditions.

iii) The STM image of the O adatom at the TFH site simulated at 70 mV has a shallow grey and white feature (Fig. 8B3) characterized with a 0.3Å indentation in the calculated profile. This feature becomes more evident at V=700 mV (Fig. 8C3). The bright lobe, however relatively smaller than the protruding features of surrounding Ag atoms, corresponds to the exact location of the O adatom while the grey-shadow is on the other side of the atomic row. Though this feature resembles the GW[001] one observed experimentally, we believe that the similarity is fortuitous since experimentally the GW is produced by merging two sombreros together (see Fig. 4C), while only one O adatom is involved in the simulated structure.

At variance with our conclusions, Hahn and Ho [43] indicated that S features were related to O adatoms at hollow and short-bridge (SB) sites, which were generated by dissociating
chemisorbed O₂ with voltage pulses at 13 K. Oxygen at the SB site was said to generate a two-lobe rather than a circular feature, and to be able to jump from one SB to another on a neighbouring row without falling into the much deeper potential wells in-between. Our STM simulations indicate, however, that O adatoms at SB sites should appear as protruding features in the STM image with ~1 Å of height from the surface (not shown here), but also that this site is unstable with respect to lateral displacements [48]. The results of ref. [43] are also at variance with our experimental findings, which shows that S features in STM images relate only to the O adatoms at LB sites. We cannot exclude, however, that O may end up at metastable sites when the adatoms are generated at 13 K from O₂ admolecules.

1.2 Grey stripes, GW oriented along [1\bar{1}0] and the observed cluster

Fig. 9A shows the optimized structure of O adatoms arranged at TFH sites in an -O-Ag-O-Ag- zig-zag chain. The Ag atoms in contact with O adatoms are vertically displaced by 0.55 Å with respect to their initial position. Such a local disorder in geometrical structure could be the consequence of the direct electrostatic interaction between Ag and O adatoms (involved in the chain). The local electronic structure varies upon the arrangement of O adatoms on the surface, thus yielding different STM features. Although the simulated STM image at 70 mV (Fig. 9B) corresponds to an internal structure corresponding to O adatoms at TFH sites, empty TFH sites and Ag atoms in the proximity of O adatoms, on average the whole zig-zag structure appears as a depression of 0.4 Å in the depth profile (Fig. 9D), with respect to the surrounding Ag atoms. Hence
it can be associated to the grey stripe (G) features observed experimentally (see Fig. 5a). At V=700 mV, the image contrast changes and O adatoms become slightly protruding but less than the neighbouring Ag atoms (consistent with the calculated density of states for O and Ag atoms, as shall be described later), while the zig-zag shape of the structure is still preserved (Fig. 9C). The STM simulation for 700 mV cannot be compared with experiment since the grey stripes are disrupted at this bias.

Fig. 10 shows the optimized geometries, the simulated STM images at V=70 mV and at 700 mV, and the corresponding line profiles of two different O-Ag-O complexes: embedded (panel A1-D1) and free (panel A2-D2). Firstly, the one reported in Fig. 10A1 (“embedded” in the following) involves one Ag atom of the surface, which is lifted by 0.56 Å from the surface plane, and two oxygen atoms in non-equivalent sites. The simulated STM images (Fig. 10B1-C1) and the line profiles (Fig. 10D1) compare nicely with the GW[1 0] features observed experimentally (see Fig. 4B4 and the measured line profile). Secondly, the free O-Ag-O complex, which can be formed upon the detachment of an embedded O-Ag-O complex and the extraction of an Ag atom, consists of an Ag adatom with two side oxygen atoms oriented along the [001] direction (“free” complex in the following). Note that the detachment process is slightly endothermic and can therefore occur spontaneously only thanks to the entropic contribution to the free energy. Based on our simulation, the detached O-Ag-O complex appears as a dumbbell in the simulated STM image at 70 mV (Fig. 10B2) and is characterized by 0.3Å depth in the calculated line profile. On the other hand, the simulated image at 700 mV appears as relatively intense protruding feature with slight change in shape and characterized by ~1 Å apparent height in the calculated profile (Fig. 10C2-D2). If there are not enough O adatoms for the formation of extended added rows, these O-Ag-O complexes may merge with semi lozenges or lozenges (as shall be described later).
**Fig. 10.** A1) Optimized geometry of a O-Ag-O complex forming upon O$_2$ dissociation on Ag(110); (B1 and C1) Simulated STM images at $V=70$ mV and $V=700$ mV, respectively; D1) Line profiles cut through the Ag adatom along [110] for $V=70$ mV (solid trace) and 700 mV (dashed trace). A2-D2) Same as A1-D1) for the free O-Ag-O complex.

Next, we simulated the STM image for the structure involving an oxygen atom buried into the octahedral interstitial immediately below an Ag atom (shown by pink ball, Fig. 11A). Our simulation indicates that such O atom together with the vertically displaced Ag atom relate to the enhanced protruding features in simulated STM image at both $V=70$ mV and 700 mV (see Fig. 11B,C), characterized by 2.4 Å and 1.8 Å heights in the line profile (Fig. 11D). This feature could partly contribute to the cluster structures observed in the experiment (Fig. 7B).

**Fig. 11.** A) Optimized geometry of O residing at the octahedral subsurface site. The Ag atom (pink ball) is located just on top of a subsurface O atom; (B-C) Simulated STM images at $V=70$ mV and $V=700$ mV, respectively; and (D) Line profiles (solid trace for 70 mV; dashed trace for $V=700$ mV).

### 1.3 Lozenges

One of the most common features at low O coverage is the lozenge (experimental data reported in Fig. 5b and Fig. 6). The O adatoms placed in the valley at 2.5 lattice spacing from one another eventually move to the FFH sites at which the structure is relaxed. The energy minimization obtained by allowing all degrees of freedom to relax thus fully reproduces the L structure. We then relax the configuration in which O adatoms are slightly off the FFH sites, by applying a constraint for O adatoms along one axis (only two degrees of freedom are allowed for relaxation). The model for lozenge is shown in Fig. 12A. The STM simulation for such configuration produces a shallow indentation with two lobes sitting in the valleys, about 0.4 Å off FFH sites. The simulated image at 700 mV (Fig. 12C) has wider indentation as compared to that obtained with 70 mV. This difference could be attributed to the local electronic effects: more electrons of Ag may participate in tunnelling current for 700 mV than for 70 mV bias. The simulated STM images both at $V=70$ mV and 700 mV
agree with the experiment. The shallow indentation in the calculated STM image is characterized by \(~0.25\text{Å}\). The calculated depth profiles nicely agree with the experiment (see Fig. 12D). These results show that lozenges consist of two O adatoms which can be stabilized by some local distortion of the substrate. Moreover, we note that if not enough O adatoms are available on the surface for the formation of extended \(-O{-}Ag{-}O\) added rows, “free” O{-}Ag{-}O complexes may merge into lozenges or semi lozenges. Indeed, the compatible half-lozenge features were occasionally observed experimentally (see e.g. Fig. 7).

**Fig. 12.** A) Optimized geometry of a configuration with two O adatoms positioned in the troughs of the Ag rows, slightly off the FFH sites, forming the lozenge (L) shaped objects. (B-C) Simulated STM images at \(V=70\text{ mV}\) and \(V=700\text{ mV}\), respectively; (D) Line profiles in the valley along \([1\ 0]\) (solid trace for 70 mV; dashed trace for \(V=700\text{ mV}\)).

### 2. Electron Density of States

According to Lang’s theory [49-51], the local density of states near the Fermi energy governs the contrast in the images of the individual adsorbates in STM. Oxygen will appear as a protrusion if it causes an increase in the local density of states compared to the silver substrate whereas it will be imaged as a depression if the local density of states is depleted with respect to the neighboring atoms on the surface.

The computed projected density of states (DOS) of the O adatoms at FFH and TFH sites, and of the Ag atoms (topmost layer) of the bare surface is shown in Fig. 13. Here, the DOS of O adatoms are deduced from the contributions from 2s and 2p orbitals, whereas those of Ag atoms of the bare surface are only plotted for s orbitals since Ag s orbitals are spread even around the Fermi level (\(E_F\)) and thus can participate in the tunneling current. As shown in Fig. 13, the Ag 5s states are dominant over the O 2p states above the Fermi level, while the O p states are dominant over the Ag states at \(-0.7\text{ eV}\) (in reference to \(E_F\)). Since the DOS is smaller for O adatoms than for Ag atoms on the surface at 70 mV and larger at 700 mV sample bias, O adatoms will normally be imaged as
depressions at low voltages and as protrusions at high voltages. Therefore, at very small bias voltage (V<0.1) O adatoms should always appear as depressions in the STM images.

Fig. 13. Electron density of states projected on the 2s and 2p orbitals of an isolated O adatom at FFH site (red solid trace) and of an O adatom at TFH site embedded in the -O-Ag-O-Ag-O- zig-zag chain (blue dotted trace) formed on Ag(110), and the 5s orbital of Ag atoms on the topmost layer (green trace) of the bare Ag(110). The energy is expressed relative to the Fermi energy (0 eV as reference level).

3. Oxygen adsorption, vacancy formation and diffusion

3.1 Adsorption of O adatoms

The binding energies of O atoms in different configurations are summarized in Table 1. Our calculations show that all considered isolated O adatom configurations are equally probable to appear on the surface since they have nearly the same binding energy to their respective sites and their wells are separated by 30-70 meV energy barriers [48]. Thus, it is not surprising that isolated O adatoms can be mobile on Ag(110). In addition, we find that O adatoms embedded in the O-Ag-O complex, the detached O-Ag-O complex, and the zig-zag chain are slightly stronger in binding than isolated ones, having binding energies per O atom of -3.98 eV, -4.12 eV and -3.99 eV respectively. The binding energy of an isolated O adatom adsorbed at the slightly preferred FFH site is -3.88 eV, followed by O adatom in TFH, and O in LB. On the other hand, the two O adatoms, adsorbed at slightly shifted FFH sites (responsible for the Lozenge feature, as discussed in earlier sub-section 1.3), gain energy when they are in pair (see Table 1). This indicates that the geometric structures for O adatoms in pair with binding energy per O atom of -3.97 eV are slightly preferred over those structures in which the adatoms are isolated. Very distinct from isolated O adatoms and
those in a pair, we find that an O in an octahedral subsurface site is energetically less favorable by 1.35 eV, 1.34 eV, and 1.32 eV than O adatoms in FFH, TFH, and LB, respectively. Thus, the various arrangements of O atoms result in different geometrical structures of O/Ag(110), suggesting different electronic and chemical properties.

Table 1. Calculated binding energy and structural parameter for O adatoms adsorbed at different adsorption sites of Ag(110) with their STM features (compatible with experiment described in subsection 1) corresponding to different structures. $E_b^{O-\text{adatom}}$ represents the binding energy per O atom, and $d_{(O-Ag)}$ represents the shortest distance between O adatom and first-nearest neighbouring Ag atom.

3.2 Vacancy formation

We now turn to discuss the energetics of Ag vacancy formation on Ag(110). Fig. 14 summarizes the vacancy formation energies on pristine low Miller index Ag surfaces, as calculated using three different theoretical methods: DFT (present study), the effective medium theory (reported in ref. [45]) and the inserted-atom method (reported in ref. [47]). The trend in the energetics for Ag vacancy formation on low Miller index surfaces is the same for all the three methods considered. Strikingly, vacancy formation is found to be much easier on Ag(110) than on Ag(100) and Ag(111) owing to the fact that fewer Ag bonds need to be broken for this surface. We find that the process is, however, always endothermic. Note that the process will not take place on Ag(110) until $T = 175$ K owing to the activation energy for the process as shall be discussed later. At finite temperature, the quantity which must be minimized is the free energy $F = E - T\Delta S$. The endothermicity of the process can thus be easily overcome by the entropic term. For Ag(110), the vacancy formation already occurs at a relatively low temperature.

![Graph](image)

Fig.14. Calculated vacancy formation energy per surface unit cell on the (111), (100), and (110) surfaces of Ag. DFT results are shown by solid squares, effective medium theory results [52] by empty squares, and results from the inserted-atom method [53] by empty circles.

Creation of Ag vacancies is favored at higher oxygen coverage on Ag(110). Fig. 15 depicts the calculated energetics of vacancy formation (i.e. Ag atom extraction) on Ag(110). It indicates that at low temperatures Ag atom extraction is not favorable unless O adatoms are present. As shown in Fig.15a, the forward process of Ag atom extraction needs to overcome a barrier of 0.69 eV, which is higher than the barrier of 0.27 eV for the backward process of filling the vacancy, and is also higher than the one for vacancy migration along [1 0] of 0.47 eV. In contrast, when O adatoms are present on the surface they facilitate the extraction of Ag atom from the surface.
Specifically, “O atoms assisted concerted motion” reduces the barrier for vacancy formation to 0.52 eV for an oxygen coverage of 0.16 ML (two O adatom per (3x4) surface unit cell), and further to 0.46 eV at 0.25 ML (three O adatoms per (3x4) surface unit cell), while the barrier for vacancy filling increases significantly (Fig. 15B,C). Therefore the presence of O adatoms on Ag(110) hinders the vacancy destruction process [see ref. 26].

Fig. 15. Energetics of atom extraction from the Ag(110) surface: A) in the absence of O atoms, B) in presence of 0.16 ML of O adatoms, C) in presence of 0.25 ML of O adatoms. Also shown are the activation energy barriers. The grey, pink and red balls represent the Ag atoms of the top layer, the Ag atom of the third layer and the O adatoms, respectively.

3.3 Diffusion of Ag vacancies

On Ag(110), vacancies can diffuse and aggregate into more complicated features. The barrier for diffusion of vacancies is highly anisotropic: along [001] it is 0.80 eV whereas it is 0.47 eV along [1\bar{1}0]. The minimum energy diffusion pathways along both directions are shown in Fig. 16. These energetics suggest that at the temperatures in our experiments vacancy migration only along [1\bar{1}0] is active and leads to the formation of multiple vacancies when their concentration is sufficiently high. Vacancies can then merge forming the body of the “butterfly” structure which was previously described in Ref. [26].
4. Kinetics of vacancy formation

In order to gain insights into the kinetics of Ag vacancy formation, we performed kinetic Monte Carlo (kMC) simulations, the results of which are summarized in Fig. 17. For completeness, we also depict the number of events for O\textsubscript{2} dissociation, which is a prerequisite for the vacancy formation process. As evident from the dotted blue curve, the maximum of O\textsubscript{2} dissociation events occurs at 157 K (for which the activation energy barrier is 0.42 eV [48]). Therefore, one could expect that, at T\geq157 K, surface Ag atoms feel strong attractive interaction with the dissociated oxygen, which may enable the formation of “embedded” O-Ag-O complexes (note that the formation of O-Ag-O complex is a spontaneous process on Ag(110)), and thus initiate the process of Ag vacancy formation. On the other hand, the solid red curve shows that the maximum of Ag-vacancy-formation events occurs at 190 K in the presence of 0.16 ML of oxygen adatoms (two O atoms per (3x4) surface unit cell). This process can be even faster when the concentration of oxygen increases since, as described above, the barrier for vacancy formation decreases with increasing O coverage. Therefore, we expect the peak temperature for vacancy formation to decrease. These kMC results are in good agreement with experimental observation.

![Fig. 17. Kinetic Monte Carlo simulation of Ag vacancy formation (solid) and O\textsubscript{2} dissociation (dashed curve) on Ag(110) at O coverage of 0.16 ML as a function of temperature.](image)

The O induced vacancy formation discussed above is actually a general phenomenon observed on a number of metal surfaces (see discussion in Ref. [26]). It has been observed also for Ag(111) [54] at much higher temperatures than reported here, in agreement with the fact that higher energy is required to break the more numerous bonds present on Ag(111).
5. Diffusion of free O-Ag-O complex

The diffusion of the detached O-Ag-O complex is anisotropic. The barrier for diffusion of the free complex along [001] is 1.30 eV whereas it is 1.46 eV for the diffusion along [1\overline{1}0] (see Fig. 18 for the minimum energy diffusion paths), indicating that the migration of the detached O-Ag-O complex along [001] is slightly preferred. Since the diffusion barriers in both cases are larger than 1 eV, the migration will not be energetically favored at low temperature, unless there is a sophisticated, lower barrier (< 1 eV) diffusion path that escapes our calculation. The free complex is therefore robust. The barrier for vacancy migration along [1\overline{1}0] is only 0.47 eV, which is smaller than that for the free complex migration along [001]. Moreover, since the free O-Ag-O complex is energetically more favorable than the other O-related structures, these complexes may eventually end up at the location where O and Ag adatoms are involved in added row formation. The detached free complexes may thus serve as building blocks for added-row structures by forming a 1D chain of O-Ag-O complex along the [001] direction. Indeed, the added rows in the STM images are immobile at 190 K [24], suggesting that these features may be robust at this temperature.

Fig. 18. Activation energy barriers of the detached O-Ag-O complex diffusion on Ag(110) along A) [001] and B) [1\overline{1}0] directions.

Together with the vacancy formation process discussed in ref. [26], the above structures, involving a displacement of Ag atoms, may contribute to the surface disorder causing the drop in elastic reflectivity of O/Ag(110) [16] in HREELS experiments.

IV. CONCLUSIONS
Our combined systematic experimental and theoretical analysis has allowed us to unravel the complex structures forming upon O\textsubscript{2} dissociation on Ag(110), which are transiently present under specific reaction conditions. We were particularly interested in identifying a variety of complex O-related features found in our STM measurements: isolated grey dots (G\textsubscript{d}), sombreros (S), shallow grey and white (GW) structures oriented along [001] and [1\overline{1}0], grey stripes (G), and lozenges (L). The accompanying DFT analysis has identify them, respectively, as: isolated O adatoms at FFH sites, O adatoms at LB sites, isolated O adatoms at TFH sites and the embedded O-Ag-O complexes, zig-zag rows of O adatoms arranged in TFH sites, and two O adatoms in the valley separated with 2.5 lattice spacing along [1\overline{1}0]. At large bias voltages (V>0.2 V), the grey stripes were disrupted giving rise to the formation of sombrero-shaped objects reported, but not assigned, in previous publications on this system [23,24]. Sombreros can be manipulated with electrical pulses at low voltage. The merging of two sombreros gives rise to the GW[1\overline{1}0] feature, which corresponds to the O-Ag-O complex embedded in the surface. The DFT-calculated binding energy per O atom ($E_b^{\text{O-\text{adatom}}}$) suggests that the formation of these O-related features is probable since they differ utmost by 200 meV.

The Ag(110) surface requires the presence of oxygen adatoms for the initial phase of local reconstruction which is subsequently followed by Ag atom extraction (formation of a vacancy), and the added-row structure formation. In STM images, the single Ag vacancies are characterized by round-shaped black dots (BDs) with their center at the Ag lattice site, whereas a pair of Ag vacancies are illustrated by an elongated BDs with its center at the SB site. Isolated Ag vacancies are mobile, but migrate in an anisotropic manner as suggested by their computed energy barriers of 0.87 eV and 0.47 eV for migration along [001] and [1\overline{1}0], respectively. They are thus mobile around 200 K, and can eventually merge together at larger coverage into rather complex, butterfly shaped features. In short, the presence of O adatoms on the surface is indispensable for vacancy formation (This process can occur at ~185-190 K as indicated by kinetic Monte Carlo simulation). Strikingly, neighboring O adatoms facilitate Ag atom extraction and help stabilize the mobile Ag atoms in the form of an oxygen-decorated Ag chain along [001] and thus ultimately induce the well-known added row reconstruction.

**ACKNOWLEDGMENTS**

We thank Robert Reichelt, Rameez Ud Din, and Angelique Lusuan for helping in different phases of the experiment. We acknowledge the financial support by ICTP through a postdoctoral grant and of Compagnia San Paolo. We acknowledge the STOKES Advanced Research Computing Center at the University of Central Florida, the National Energy Research Scientific Computing Center.
(NERSC), and the Center for Nanoscale Materials (CNM) of the Argonne National Laboratory for providing the computer resources. TBR, SH and TSR thank Duy Le for fruitful discussion on simulated STM images and US NSF for the partial support under grant CHE-1310327.
