Abstract

We demonstrate deterministic control of dipole-field-stabilized skyrmions by means of spin-orbit torques arising from heavy transition-metal seed layers. Experiments are performed on amorphous Fe/Gd multilayers that are patterned into wires and exhibit stripe domains and dipole skyrmions at room temperature. We show that while the domain walls and skyrmions are achiral on average due to lack of Dzyaloshinskii-Moriya interactions, the Néel-like closure domain walls at each surface are chiral and can couple to spin-orbit torques. The current-induced domain evolutions are reported for different magnetic phases, including disordered stripe domains, coexisting stripes and dipole skyrmions and a closed packed dipole skyrmion lattice. The magnetic textures exhibit motion under current excitations with a current density \(\sim 10^8\) A/m\(^2\). By comparing the motion resulting from magnetic spin textures in Fe/Gd films with different heavy transition-metal interfaces, we confirm spin currents can be used to manipulate achiral dipole skyrmions via spin-orbit torques. We further show the current-induced response of a dipole skyrmion lattice where skyrmions move in channels between pinned regions.
Introduction.

The ability to locally control magnetism through the use of electrical currents has led to the development of a range of new non-volatile and efficient magnetism-based information technologies [1-3]. Current-induced magnetization dynamics were initially observed from spin-transfer torques in nanopillar devices with two magnetic layers [4-7]. The current becomes spin polarized by transmission through or upon reflection from the first magnetic layer and maintains this polarization as it passes through the non-magnetic spacer and interacts with the second ferromagnetic layer. This interaction provides a torque on the magnetic driving precessions that can result in steady-state magnetic dynamics or magnetization reversal [8-11]. A similar phenomenon occurs in magnetic wires where spin current exerts a torque on the domain wall that enables their displacement in the electron flow direction [12-16].

The discovery of spin-orbit torques (SOT) arising from current-induced spin accumulation at the interface between a ferromagnetic layer and a non-magnetic layer with a large spin-orbit coupling (e.g. a heavy transition metal) provides an efficient method for manipulating spin structures within a single magnetic layer. The spin currents arise from the spin Hall effect in the non-magnetic metal layer when a charge current flows within the sample plane. The spin Hall effect generates a spin current that flows vertically towards the ferromagnet. When this spin current is absorbed in the ferromagnetic it applies a SOT. This torque is particularly effective at moving chiral domain walls or skyrmions stabilized by interfacial Dzyaloshinskii–Moriya interaction (DMI) that arise at the interface of the magnetic-nonmagnetic interface. The direction of motion is set by the helicity of the spin structure and the sign of the spin Hall angle in the non-magnetic layer. These observations demonstrated that magnetic spin textures could be displaced with low currents [17-27] in either patterned films [17-26] or continuous geometries [27]. These observations prompted research efforts to potentially develop next-generation high-efficiency and high-density information technologies in which individual skyrmions or chiral domain walls are used as logic and memory storage bits [28-32].

Thus far, the motion of chiral domain walls and skyrmions in thin films have been stabilized by interfacial DMI where the heavy-metal layer has the dual role of providing both the SOT and the DMI to stabilize the appropriate chiral spin structure. Here, we present direct observation of current-induced motion of magnetic stripe domains and dipole skyrmions in patterned wires of amorphous Fe/Gd multilayers at room temperature without the presence of
DMI. The formation of sub-100nm dipole-stabilized biskyrmions and skyrmions in this class of material were previously reported in Refs. [33] and [34], respectively. These magnetic textures result solely from the competition between magneto-static and exchange energies [34] and there is no evidence of DMI in this system. Unlike skyrmions that form by means of DMI, a dipole skyrmion phase consists of an equal population of chiral cylindrical-like domains with two possible helicities (Fig. 1a, b) such that, on average, the material is achiral. This has been shown in Lorentz transmission electron microscopy which confirmed the dipole skyrmions possess a Bloch-like domain wall with equal population of two helicities for dipole-stabilized skyrmions in comparable Fe/Gd films [34].

In the currently studied Fe/Gd multilayer the thin-film shape anisotropy $2\pi M_S^2$ exceeds the uniaxial anisotropy $K_U$ so the ratio $Q = K_U / 2\pi M_S^2 < 1$ [35], the dipole skyrmion phase becomes favorable for relatively thick magnetic films. For such films, numerical simulations predicted that dipole skyrmions possess a domain wall that is Bloch-like at the center of the film but broadens and transitions to Néel-like walls towards the film surface (Figs. 1a, b) which are often referred to as closure domains or Néel caps [36]. While the Bloch nature of wall in the center of the film will have one or two possible helicities shown in the Figs. 1a, b, the Néel-wall structure of the spins near the surfaces of the film have the same helicity for the top surface and the opposite helicity at the bottom surface (thus in total the spin structure is achiral). For the examples shown in Figs. 1a and b the magnetic spins at the top surface point inwards into the skyrmion whereas at the bottom surface they point outwards from the dipole skyrmion and this is independent of the helicity of the Bloch-wall in the core. The chiral nature of the surface spins in closure domains, even in the absence of DMI, has previously been shown by x-ray resonant magnetic scattering from stripe domains using circularly polarized soft x-rays [37] and have been recently observed in chiral magnetic spin textures stabilized by DMI in bulk magnets [38] and thin film heterostructures [39-41]. Here, we demonstrate that SOT can be used to manipulate dipole skyrmions, by interfacing the dipole-stabilized chiral surface spin structures of Fe/Gd films with heavy transition metal layers (e.g. Pt, Ta). Our results show the current-driven motion of dipole skyrmions depends, as expected, on the sign of the spin Hall angle of the transition metal layer and the chirality of the near-surface region of the stripe domains and dipole skyrmions.

**Experimental methods and results.**
The amorphous [Fe(0.34nm)/Gd(0.4nm)]\textsubscript{N} multilayer films were fabricated by magnetron sputtering at room temperature in a 3-mTorr Ar pressure. The chamber base pressure was < 3x10\textsuperscript{-8} Torr. The multilayer films were grown by alternatively depositing Fe and Gd layers for N repetitions with different seed and capping layers. The Fe and Gd layer thickness values were optimized to achieve the skyrmion phase at room temperature [34]. Selected Fe/Gd films were deposited onto photolithographic defined wires on 100-nm-thick SiN membranes with 5x5mm frames and 1mm x 1mm windows. Transition metal Pt and Ta seed and capping layers were used to protect the specimen from corrosion. Fe/Gd full films were also deposited onto Si-substrate with a native-oxide layer for magnetometry measurements and SiN membranes to serve as reference samples.

**Domain morphology of Fe/Gd patterned wires.**

The magnetic domains at remanence were imaged using scanning electron microscopy with polarization analysis (SEMPA) at the National Institute of Standards and Technology in Gaithersburg, MD. The field-dependent magnetic domains in patterned wires were imaged using full-field soft x-ray transmission microscopy at Lawrence Berkeley National Lab, Advanced Light Source, Beamline 6.1.2 along the Fe \textsubscript{L3} (708eV) absorption edge. Figures 1c – e shows SEMPA images of the stripe domains in remanence. This technique is surface sensitive and can image the projection of the magnetic spin x, y and z directions. Figures 1c-e detail the surface \((m_x, m_y, m_z)\) magnetization distributions, where the perpendicular stripe domains with opposite orientation are represented along the \((m_z)\) magnetization as dark/light contrast, whereas the Néel closure domains are solely seen by the periodic \((m_x)\) magnetization consistent with the schematic in Figs. 1a and 1b. No contrast is observed along the \((m_y)\) direction, as expected for vertically-oriented stripe domains. This clearly shows the expected closure domain structure for the stripe phase. Because this imaging technique is sensitive to external magnetic fields we cannot image the surface domain structure in an applied field.

The field-dependent domain morphology and its current-induced motion were studied using full-field transmission soft x-ray microscopy measured at the Fe \textsubscript{L3} (708eV) absorption edge in 10-μm wide and 5-mm long Fe/Gd patterned wires (see Methods, for further details). Figures 1f-h shows the domain morphology of the Pt(5nm)/[Fe(0.34nm)/Gd(0.4nm)]\textsubscript{100}/Ta(3nm) wire sample imaged while a perpendicular magnetic field was applied from negative to positive magnetic saturation. Each image details the
perpendicular magnetization averaged over the thickness of the film. At remanence (Fig. 1f), the film exhibits stripe domains with a stripe periodicity of 180 nm consistent with Fig. 1c imaged for a full film. The stripe domains are preferentially aligned in the direction of the Fe/Gd wire length. Under a perpendicular field, we observed first coexisting stripe domains and dipole skyrmions (Fig. 1g) and then a closed packed lattice of dipole skyrmions (Fig. 1h) which is similar to the results of Ref. [34]. The dipole skyrmion features are 90 nm in diameter at \( H_z = +2000 \) Oe. Limitations in the applied magnetic field did not allow the observation of the disordered dipole skyrmion phase and saturation, as previously reported in Ref. 31. The saturation field for this Fe/Gd wire exists above \( H_z > 2800 \) Oe, which is above the maximum applied magnetic field of the microscope.

**Current-induced dynamics of stripe domains and dipole skyrmions.**

We applied current pulses to the wire samples and imaged the evolution of domain structure under current. The domain morphology at any given field was recorded prior to the application of an electrical current pulse. For the measurements presented, we used 10-\( ms \) long current pulse with amplitude up to \( j = 5 \times 10^8 \) A/m\(^2\). After the current excitation pulse, the domain morphology was again recorded. This process was repeated until collecting several frames. Afterwards, the magnetic field history was cycled (e.g. the magnetic field was increased to magnetic saturation and then the field was reduced to the opposite magnetic saturation field, prior to returning to the desired magnetic field). In order to clearly identify current-induced motion of magnetic textures, an area of the wire with a defect within the field of view was chosen to facilitate alignment between image snapshots. Each snapshot results from a 2-sec exposure and 5 averages.

Figure 2a shows the domain morphology of coexisting stripe domains and dipole skyrmions that form in Pt(5nm)/[Fe(0.34nm)/Gd(0.4nm)]x100/Ta(3nm) film under a perpendicular field of \( H_z = +1250 \) Oe. We applied a series of 10-\( ms \)-long current pulses with density amplitude of \( j = 5 \times 10^8 \) A/m\(^2\). We generally observe that the first current pulse alters the domain structures (e.g. converting stripes into skyrmions) and then subsequent current pulses induce directional motion of the domains. Figures 2b-d shows a sequence of snapshots of the evolution of the domain states when these are subjected to a sequence of single current pulses. Depending on the current pulse iteration, denoted \( p_1, p_2, \) and \( p_3 \) in Figs. 2a-d, we find there is a mixture of pinned and moving dipole skyrmions. By tracking the current-induced motion of
dipole skyrmions, we observe these textures move in the direction of the current flow. Example dipole skyrmions that are continuously displaced under the application of the current pulses have been outlined in Figs. 2a-d. When the electrical current is reversed (Figs. 2e-h), we observe the dipole skyrmions move opposite to the original direction and again along the current flow direction. Since the motion is along the current flow direction we attribute the motion arises by SOT from the Pt seed layer acting on the chiral spin structure at the bottom interface and the direction of propagation is consistent with the results of Ref. 16. The top Ta layer is thinner and partially oxidizes and therefore we expect it to contribute far less to the domain motion.

To further probe the driving mechanism that results in current-motion of dipole skyrmions, we have also studied the current dynamics for a Ta(5nm)/[Fe(0.34nm)/Gd(0.4nm)]x100/Pt(3nm) film (Fig. 3) where the materials of the seed and capping layers are inverted. Since heavy transition metals Pt and Ta have opposite sign of the spin Hall angle [42, 43], we expect the motion of dipole skyrmions with respect to the current flow to be reversed if SOT is the driving mechanism. Figure 3a shows the domain morphology, primarily consists of stripe domains and a few dipole skyrmions when the film is exposed to a magnetic field of $H_z = -875$ Oe (Fig. 3a). After the first current pulse, most of the stripe domains collapse into a collection of dipole skyrmions that occupy the region previously filled by the original stripe domain (Fig. 3b). In the previous magnetic film (Fig. 2) there was limited evidence of stripe domains collapsing into dipole skyrmions. As discussed in Ref. [34], we find that dipole skyrmions can form by two mechanisms: (i) the extremities of a single stripe domain can collapse to form a dipole skyrmion, or (ii) a single stripe domain can pinch into a line of dipole skyrmions where the stripe domain previously existed. Both these mechanisms were previously observed in Fe/Gd films [34] and appear to be favored under different ratios of magnetic energies suggesting these Fe/Gd wires possess small differences in magnetic properties for different seed layers. Figures 3b-e detail subsequent snapshots of the domain morphology after iterative single electrical pulse excitations. Once the film primarily consists of dipole skyrmions, the current-driven stripe to dipole skyrmion transformation is no longer predominant. After the first pulse there is a mixture of pinned and moving dipole skyrmions; however, the displacement of dipole skyrmions is now in the direction of the electron flow (Figs. 3b-e). Examples of moving dipole skyrmions have been outlined in Figs. 3a-e. When the magnetic field is reversed, $H_z = +875$ Oe, we observe comparable current-induced dynamics of the magnetic textures as outlined for $H_z = -875$ Oe, and
dipole skyrmions again displace along the electron flow (Fig. 3f-j). As discussed below, this is expected as the chirality of the surface closure domains remains the same after inverting the field. Further imaging of stripe domain response to current pulses including current induced stripe-to-skyrmion generation are shown in Supplementary Sections 1 and 2 [44].

**Current-induced motion in dipole skyrmion lattice.**

We also investigated the current-induced dynamics that results from a closed packed lattice of dipole skyrmions using current pulse excitations. Figure 4 shows the domain morphology of Ta(5nm)/[Fe(0.34nm)/Gd(0.4nm)]×100/Pt(3nm) that forms under a perpendicular magnetic field of $H_z = -2250$ Oe (Fig. 4a). The dipole skyrmion features are 85 nm in diameter and arrange in a disordered closed-pack array. When a current pulse is injected, complex motion is observed throughout the field-of-view (Supp. Movie [45]). It is difficult to track individual dipole skyrmions by comparing before/after static images because these textures are arranged in a closed packed lattice making the identification of individual skyrmions difficult. To illustrate dipole skyrmion motion, we have processed the raw images, such as the one shown in Fig. 4a, to remove the background and construct binary images. Figure 4b shows the post-processed image that was obtained from Fig. 4a where the white regions are the skyrmions. Changes in the domain morphology with current pulses are outlined as contrast changes that result from the summation of binary images obtained before/after a current pulse is applied. Figures 4c-f show the domain motion that result from four iterative single current pulses where the skyrmions that are pinned appear as white domains in the summation (i.e. did not move under current) and skyrmions that move will yield an intermediate contrast. We observe there are regions of pinned dipole skyrmions coexisting with moving dipole skyrmions. The displacements of dipole skyrmions are in the form of river-like channels that are oriented at various angles relative to the electron flow. By inspecting the snapshots of the domain morphology (Figs. 4c-f) we are able to track the skyrmion positions and determine an average skyrmion speed $<s> = 6 \mu m/s$ when exposed to a single current pulse.

Figure 5 shows the current-induced dynamics of a closed packed lattice of dipole skyrmions under the application of a single current pulse with different current density amplitude which reveal the transition from the pinned to creep regime. To highlight the motion of the skyrmions the domain images are converted into binary images as described earlier. After a series of current pulses are injected, at a current density amplitude, the domain morphology is reset by cycling the
perpendicular field up to positive saturation, then reducing the field to negative saturation, and finally increasing the field up to $H_z = +2000$ Oe under which a closed-packed lattice of dipole skyrmions forms. We observe the transition from the pinned to creep regime with increasing current density amplitudes from $j = 0.5 \times 10^8$ A/m$^2$ to $j = 5 \times 10^8$ A/m$^2$ (Fig. 5). Current amplitudes below $j < 3 \times 10^8$ A/m$^2$ exerts a weak SOT that is unable to displace the textures from their pinning site. Figures 5a-c show the domain states after the injection of three iterative current pulses with amplitude $j = 0.5 \times 10^8$ A/m$^2$, where there is evidence of minor changes in contrast around many of the individual textures. The latter results from illumination artifacts when recording domain morphology snapshots. Increasing the current density amplitude, $j > 3 \times 10^8$ A/m$^2$, we observe the number of dipole skyrmions exhibiting motion increases from a few clustered textures in scattered regions across the field-of-view to many textures that form river-like channels (Fig. 5d-l).

**Discussion.**

Since the closure domains of a dipole skyrmions possess an opposite Néel-like chiral structure on the top and bottom surface (Fig. 1a, b) and heavy transition metal interfaces with different spin Hall angle, we can expect the coupling to spin currents will be asymmetric at the top and bottom surface. The latter results in a dipole skyrmion experiencing an opposite SOT at each surface. Since the SOT depends on the spin-Hall angle [42, 43] and thickness [46, 47] of the heavy transition metal, we expect the force amplitude is different at both surfaces. Since the observed directions of the skyrmion motion can be explained by the combination of chirality of the Néel caps and the SOT at the bottom surface, we conclude that the SOT arising from the thicker seed layer plays a dominant role in the motion of dipole skyrmions. Results in Figs. 2 and 3 show there is a dependence in the direction of dipole skyrmion motion relative to inverting the seed/capping layers. A more efficient displacement of dipole skyrmions will likely result when using the same heavy transition metal at both surfaces, as well as, reducing the total thickness of the magnetic specimen such that the SOT efficiency increases [48]. Also motion of skyrmions would be more efficient if we could image at higher fields where individual skyrmions can be isolated. In the present experiments we have closed packed domain structures so stripe-skyrmion or skyrmion-skyrmion interaction limits the mobility giving the relative low velocities observed. Finally, we note that evidence of SOT driving the motion of dipole skyrmions is also supported by the observation of stripe-to-skyrmion generation [49].
Our results on the current-induced motion in the skyrmion lattice phase are similar to a recent numerical study of skyrmion lattices in the presence of disorder [50]. Using a particle-based model of a modified Thiele equation, these authors predicted the skyrmion Hall effect depends on the drive force acting on the skyrmions as well as the pinning force that arises from defects. The study anticipates that: (i) under weak drive forces, the skyrmion Hall angle is not constant and skyrmion motion is oriented in scattered directions; (ii) Increasing the drive force acting on the skyrmions, median drive force, results in the river-like motion that is oriented at an angle relative to the direction of the drive force. (iii) Only after a sufficiently high drive force is applied, do all the skyrmions domains move uniformly along the skyrmion Hall angle. In our Fe/Gd films, we appear, within the context of this model, to be inducing dipole skyrmion motion in the creep regime under a median drive force. We find that reducing the current pulse amplitude to \( j = 3 \times 10^8 \, \text{A/m}^2 \) results in motion of clustered dipole skyrmions in random regions within the field-of-view, as numerically predicted by Ref. [50] under the application of a weak drive force. Because of instrumentation limitations, we were unable to inject higher amplitude current pulses (e.g. high drive force regime) to observe dipole skyrmion motion in the flow regime. We expect that skyrmion Hall effect [51-54] would be manifested by dipole skyrmions in the flow regime, such that dipole skyrmions with clockwise (Fig. 1a) and counter-clockwise (Fig. 1b) Bloch helicity component would displace tangentially in the same direction [55-58] based on their common topological charge; however, in the case of damping-like SOT the mixed chirality can play a role in the experimentally measured skyrmion Hall angle [58].

In conclusion we demonstrated that sub-100nm dipole skyrmions can be manipulated with spin currents via spin-orbit torque. We have experimentally verified the presence of closure domains in our Fe/Gd films which supports the numerically predicted spin structure of dipole skyrmions that form in magnets with a \( Q \)-factor < 1. The observation of complex and non-trivial current dynamics resulting from large ensemble of magnetic spin textures illustrates the importance of understanding pinning and repulsive forces. The ability to manipulate dipole skyrmions with spin currents encourages potential implementation into spintronic based devices and sensors.
