(Dated: November 26, 2018)

Recent thermal conductivity measurements on Sr$_2$RuO$_4$ [E. Hassinger et al., Phys. Rev. X 7, 011032 (2017)] were interpreted as favoring a pairing gap function with vertical line nodes while conflicting with experiments probing the low energy excitations. Since deep gap minima are not protected by any symmetry, unlike symmetry-enforced nodes, their occurrence in Sr$_2$RuO$_4$ requires some explanation. In the calculations of Refs. 21 and 23 deep gap minima appear on the α and β FS sheets, which are generated by small hybridizations of the Ru 4$d_{xz}$ and 4$d_{yz}$ quasi-one-dimensional (1$d$) bands. These gap minima are vertical as they exist at all values of $k_z$. If we ignore the hybridization as well as small couplings to the γ-band, the near nesting of the quasi-1$d$ bands and the corresponding peak in the anti-ferromagnetic spin fluctuation spectrum at the nesting wavevector $Q$ favor $p$-wave superconducting order parameters with accidental nodes on each quasi-1$d$ band.

I. INTRODUCTION

Understanding unconventional superconductors, including both their pairing symmetries and mechanisms, has been a great challenge. Among the many unconventional superconductors discovered, Sr$_2$RuO$_4$ is thought to realize a spin triplet chiral $p$-wave superconductor. However, despite more than twenty years of study the exact nature of its superconducting order parameter remains a puzzle, which is partially due to conflicting interpretations of different experiments. The proposal of spin triplet chiral $p$-wave pairing has been supported by many experiments. Spin susceptibility measurements on Sr$_2$RuO$_4$, including nuclear magnetic resonance and polarized neutron scattering, do not see any drop of the electronic spin susceptibility below the superconducting transition temperature $T_c$, consistent with spin triplet pairing. Further support for chiral $p$-wave pairing comes from the spontaneous time reversal symmetry breaking revealed by muon spin relaxation and polar Kerr effect measurements. In its simplest form, chiral $p$-wave pairing gives rise to a full gap on the entire Fermi surface (FS) sheets of Sr$_2$RuO$_4$, which, however, is incompatible with experiments probing the low energy excitations. These include specific heat, ultrasound, and penetration depth measurements, all of which imply that low energy excitations exist deep inside the superconducting state. In order to account for these experiments, chiral $p$-wave pairing gap functions with deep minima (or accidental nodes) have been proposed and supported by microscopic calculations.

Since deep gap minima are not protected by any symmetry, unlike symmetry-enforced nodes, their occurrence in Sr$_2$RuO$_4$ requires some explanation. In the calculations of Refs. 21 and 23 deep gap minima appear on the α and β FS sheets, which are generated by
This is consistent with the well-known universal thermal transport\textsuperscript{29–31} of a superconducting state with line nodes; while it is completely different from what is expected for the isotropic chiral \textit{p}-wave case. For isotropic chiral \textit{p}-wave, the residual thermal conductivity becomes vanishingly small\textsuperscript{32,33} in the zero impurity scattering limit, since the number of low energy excitations available for heat transport decreases rapidly below the isotropic superconducting gap and impurity induced sub-gap states are localized\textsuperscript{34}.

Despite their consistency with the thermal conductivity data\textsuperscript{23}, vertical line nodes are, generically, not compatible with a time reversal symmetry breaking superconducting state in Sr\textsubscript{2}RuO\textsubscript{4} due to Blount’s theorem\textsuperscript{19}. Therefore, it is useful to consider vertical near-nodes in order to reconcile the time reversal symmetry breaking with the thermal transport measurements.

Although it is well known that near-nodes or accidental nodes in an \textit{s}-wave superconductor can be easily washed out by impurity scattering\textsuperscript{23} the effect of disorder on accidental nodes or near-nodes in a non-\textit{s}-wave superconductor has not received much attention, largely because non-\textit{s}-wave superconductors typically have symmetry protected nodes that dominate the low-temperature behavior, while accidental nodes or near-nodes are much less common and typically require fine-tuning of microscopic parameters. However, this issue becomes important in a multi-component non-\textit{s}-wave superconductor like chiral \textit{p}-wave in Sr\textsubscript{2}RuO\textsubscript{4} that does not have any symmetry protected nodes.

A key point is that \textit{s}-wave and non-\textit{s}-wave behave very differently in this respect. Unlike in an \textit{s}-wave superconductor, accidental nodes or deep minima in a non-\textit{s}-wave superconductor can be robust to impurity scattering and lead to a dependence of the residual thermal conductivity on the normal state impurity scattering rate \(\Gamma_N\), similar to that of the \textit{d}-wave pairing case, provided \(\Gamma_N \gtrsim \Delta_{\text{min}}\) (we set \(\hbar = 1\)). Here \(\Delta_{\text{min}}\) is the minimum zero temperature gap magnitude. The explanation for the difference is essentially the same as the explanation for why \textit{s}-wave is robust to non-magnetic potential scattering disorder, while non-\textit{s}-wave is easily destroyed by such disorder. At low temperature, impurities scatter Bogoliubov quasiparticles around the Fermi surface, effectively averaging the gap function (not the gap magnitude) around the Fermi surface, which leads to a robust, isotropic gap with deep minima at all \(\mathbf{k}\) for non-\textit{s}-wave pairing. In the self-consistent \textit{T}-matrix formalism, used in this paper, this impurity-averaging effect adds a self-energy off-diagonal in the Nambu particle-hole space, \(\Sigma_{\text{o,d}}(\omega)\), to the original anisotropic clean system gap function \(\Delta(\mathbf{k},\omega) = \Delta(\mathbf{k}) + \Sigma_{\text{o,d}}(\omega)\). To first order in the impurity concentration, \(\Sigma_{\text{o,d}}(\omega) \propto \langle \mathcal{F}(\omega,\mathbf{k}) \rangle_{\text{FS}}\), where \(\mathcal{F}\) is the clean system anomalous Green’s function and \(\langle \cdots \rangle_{\text{FS}}\) denotes an average over the Fermi surfaces. For \textit{s}-wave, \(\Sigma_{\text{o,d}} \neq 0\) and effectively gaps out the accidental nodes. For non-\textit{s}-wave, the FS average is zero, so \(\Sigma_{\text{o,d}} = 0\) and the disorder averaged gap function (while reduced overall) has the same anisotropy and deep gap minima as the clean \(\Delta(\mathbf{k})\). Furthermore, if \(\Gamma_N \gtrsim \Delta_{\text{min}}\), the impurity induced states below \(\Delta_{\text{min}}\) are delocalized. Consequently, the effect of disorder on near-nodes or accidental nodes in a non-\textit{s}-wave superconductor is similar to the effect on symmetry protected nodes provided \(\Gamma_N \gtrsim \Delta_{\text{min}}\), which only requires a tiny amount of disorder if \(\Delta_{\text{min}}\) is very small.

In this paper, we support the above arguments with explicit residual thermal conductivity calculations for different chiral \textit{p}-wave pairing models, proposed for Sr\textsubscript{2}RuO\textsubscript{4}, that have deep minima and study in some detail the constraints that experiments place on such models. Our calculations use the self-consistent \textit{T}-matrix approximation (SCTA) and the self-consistent Bogoliubov de Gennes (BdG) equations. An analysis of the residual thermal conductivity within the SCTA in Appendix\textsuperscript{B} shows that the substantial residual thermal conductivity at \(\Gamma_N \gtrsim \Delta_{\text{min}}\) also implies delocalized zero-energy Bogoliubov quasiparticle states; while for \(\Gamma_N \lesssim \Delta_{\text{min}}\) the zero energy states tend to localize. Since SCTA is only approximate, we also analyze the effects of disorder using self-consistent BdG which includes scattering effects beyond the SCTA and allows local order parameter variations. These calculations confirm which states are localized or delocalized and show that our conclusions remain valid beyond the SCTA.

The effects of impurity scattering on chiral \textit{p}-wave pairing with deep minima have been studied for Sr\textsubscript{2}RuO\textsubscript{4} previously in Refs.\textsuperscript{19} and\textsuperscript{20} However, Ref.\textsuperscript{19} focuses on the impurity induced residual density of states and its thermodynamic signatures rather than transport; Ref.\textsuperscript{20} has calculated thermal conductivity in the presence of disorder within the SCTA, but only for a particular impurity concentration. Neither studies the effect of different amount of disorder on the residual thermal conductivity which is the focus of this paper. Furthermore, the impurity concentration considered in Ref.\textsuperscript{20} is too small for a direct comparison to experiments\textsuperscript{28,32} (for more detailed discussions, see Sec.\textsuperscript{11A}).

Although, deep gap minima in chiral \textit{p}-wave can lead to a residual thermal conductivity similar to \textit{d}-wave, the fact that the experimental data is well fit by assuming \textit{d}-wave on all three bands does place considerable constraints on models of chiral \textit{p}-wave with near-nodes. These constraints are explored here by considering several different chiral \textit{p}-wave models, including the possibility of horizontal line nodes which have been invoked to explain some experiments on Sr\textsubscript{2}RuO\textsubscript{4}\textsuperscript{20,19}

The paper is organized as follows. In Sec.\textsuperscript{II} we describe the residual thermal conductivity calculation for various pairing models\textsuperscript{21,23,26,11} and compare the results with experiments\textsuperscript{28,32} in Sec.\textsuperscript{III} In Sec.\textsuperscript{IV} we present a self-consistent BdG analysis which confirms the SCTA and shows that the impurity induced states below \(\Delta_{\text{min}}\) are delocalized for \(\Gamma_N \gtrsim \Delta_{\text{min}}\). Sec.\textsuperscript{V} contains conclusions and further discussions. Appendix\textsuperscript{A} and\textsuperscript{D} provide some technical computational details and further discus-
II. RESIDUAL THERMAL CONDUCTIVITY IN THE SCTA

We first outline the general procedure of the residual thermal conductivity calculation within the SCTA for a general BdG Hamiltonian, \( \hat{H}_{\text{BdG}}(k) \), which may consist of two or three orbitals/bands.

Consider an \( N \)-band BdG Hamiltonian, \( \hat{H}_{\text{BdG}}(k) \), which is a \( 2N \times 2N \) matrix. We denote all matrix quantities with a hat. The clean system Green’s function, \( G_0(i\omega_n,k) \), is defined from its inverse:

\[
\hat{G}_0^{-1}(i\omega_n,k) \equiv i\omega_n - \hat{H}_{\text{BdG}}(k),
\]

where \( \omega_n = (2n+1)\pi T \) is the fermionic Matsubara frequency and \( T \) the temperature which will be set to zero at the end. The effect of impurity scattering on the Bogoliubov quasiparticles is included via an impurity self energy, \( \Sigma(i\omega_n,k) \). The momentum \( k \) is still a good quantum number because the translational symmetry is restored after the impurity potential configuration averaging. We take the impurity scattering potential to be isotropic and completely \( k \) independent, so, in \( k \) space, \( \hat{V}_{\text{imp}} = V_0 1_{N \times N} \), where \( V_0 \) is a constant and \( 1_{N \times N} \) is the identity matrix in the orbital sub-space. As argued in Refs. [19, 25] and [6], the impurity scattering in Sr2RuO4 is in the unitary scattering limit; \( V_0 \to \infty \), which will be taken in our calculation. Since \( \hat{V}_{\text{imp}} \) does not depend on \( k \), \( \Sigma(i\omega_n,k) \equiv \bar{\Sigma}(i\omega_n) \) is independent of \( k \) as well, and within the SCTA, is given by [19, 26]

\[
\bar{\Sigma}(i\omega_n) = \frac{n_i \hat{V}_{\text{imp}} \tau_3}{1 - G(i\omega_n)\hat{V}_{\text{imp}} \tau_3},
\]

where \( n_i \) is the impurity concentration and \( \tau_3 \) is the \( z \)-component Pauli matrix of the particle-hole Nambu sub-space. For a general superconductor, all \( 2N \times 2N \) matrix elements of \( \Sigma \) can be nonzero. However, for a non-s wave superconductor, the anomalous part of \( \Sigma \) is always identically zero [26, 27] and \( \Sigma \) has at most \( 2N^2 \) nonzero elements. For \( V_0 \to \infty \), the impurity scattering strength is solely characterized by \( n_i \), which is directly proportional to the normal state impurity scattering rate, \( \Gamma_n \). In the denominator of Eq. (2), \( \bar{G}(i\omega_n) \) is the \( k \)-space averaged Green’s function

\[
\bar{G}(i\omega_n) = \frac{1}{N_k} \sum_k \hat{G}(i\omega_n,k),
\]

where \( \frac{1}{N_k} \sum_k \) means averaging over the first Brillouin zone and \( \hat{G}(i\omega_n,k) \) is the full disorder averaged Green’s function, defined by

\[
\hat{G}^{-1}(i\omega_n,k) = \hat{G}_0^{-1}(i\omega_n,k) - \Sigma(i\omega_n).
\]

For a given BdG Hamiltonian and \( n_i \), Eqs. (1)-(4) form a set of closed self-consistent equations for the impurity self energy matrix \( \Sigma(i\omega_n) \) and can be solved numerically by iteration.

However, the non-magnetic impurity scattering is also pair breaking for non-s wave superconductors, and degrades the superconducting order parameter \( \Delta(k) \) that enters into the BdG Hamiltonian of the above equations. This is taken into account by supplementing Eqs. (1)-(4) with the superconducting gap equation for \( \Delta(k) \). We start with the gap function in the orbital basis, \( \Delta(k) \), which is a diagonal matrix in all the models that we study: \( \Delta(k)_{\alpha,\beta} = \Delta_\alpha(k)\delta_{\alpha,\beta} \) with orbital labels \( \alpha = 1, ..., N \). Then we perform a unitary transformation on \( \Delta(k) \) to obtain the gap functions in the band basis, \( \Delta^b(k) \equiv \bar{U}^\dagger_k \Delta(k) \bar{U}^\dagger_k \), where \( \bar{U}_k \) is the unitary matrix that diagonalizes the normal state Hamiltonian at the wavevector \( k \). In general, \( \Delta^b(k) \) is not diagonal in the band basis, meaning some inter-band pairing has been included. However, these inter-band pairing terms are small over most of the FS and, also, the lowest lying Bogoliubov quasiparticle energies do not depend on them to leading order in the overall gap magnitude [58].

As a consequence, the inter-band pairing terms do not have any noticeable effect on the residual thermal conductivity. Therefore, we will neglect them in the SCTA calculation so that there is only one pairing gap equation for each diagonal component of \( \Delta^b(k) \). (However, we note that the BdG analysis in Sec. IIIV does include inter-band pairing.) If we write these diagonal components as \( \Delta^b_{\alpha,\alpha}(k) = \Delta_\alpha f_\alpha(k) \), where \( \Delta_\alpha \) is the overall pairing magnitude of the \( \alpha \)-th band and \( f_\alpha(k) \) is the corresponding dimensionless gap function, then the gap equations to be solved are given by

\[
\Delta^b_\alpha = V_\alpha \pi T \sum_n \frac{1}{N_k} \sum_k f_\alpha^*(k) F_\alpha(i\omega_n,k),
\]

where \( F_\alpha(i\omega_n,k) \equiv \bar{G}^b_{\alpha,\alpha+N}(i\omega_n,k) \) is the \( \alpha \)-th band anomalous Green’s function. The superscript \( b \) in \( \bar{G}^b_{\alpha,\alpha+N} \) means \( \Delta^b \) is the band basis Green’s function (disorder averaged), obtained from the orbital one by \( \bar{G}^b(i\omega_n,k) = \bar{U}^\dagger_k \bar{G}(i\omega_n,k) \bar{U}_k \) with \( \bar{U}_k \equiv \text{diag}(\bar{U}_k, \bar{U}^*_k) \). \( V_\alpha < 0 \) is the attractive pairing interaction strength for the \( \alpha \)-th band. In writing down the above gap equation we have assumed that the effective pairing interaction for the \( \alpha \)-th band takes the factorizable form, \( V^\alpha_{\text{BCS}}(q,k) = V_\alpha f_\alpha(q)f_\alpha^*(k) \), such that it reproduces the desired pairing channel for the \( \alpha \)-th band. The magnitude of \( V_\alpha \) is determined by the clean system pairing gap magnitude. Furthermore, we have assumed that the pairing interaction is not affected by the impurity scattering.
Since the pairing magnitude, $\Delta_b$, is non-degenerate for different bands, in general, we need to solve all $N$ pairing gap equations simultaneously. Also the critical impurity concentration, $n_{i,c}$, is defined as the one at which all $\Delta_b$ vanish. Solving the coupled Eqs. (1)-(5) numerically by iteration (for $T = 0$) we obtain both the disorder averaged Green’s functions and the disorder averaged pairing gap magnitude.

With the above information we can compute the residual thermal conductivity $\kappa_0(n_i)$, defined by $\kappa_0(n_i) \equiv \lim_{T \to 0, \Omega \to 0} \frac{\kappa(\Omega, T)}{T}$, where $\kappa(\Omega, T)$ is the frequency $\Omega$ and temperature $T$ dependent thermal conductivity. Note that $\kappa_0$ depends on $n_i$. Following Ref. 29, we start with the thermal current operator matrix, $\hat{j}(\Omega, q \approx 0) = \sum_{k} (\omega + \Omega) \hat{\Psi}^\dagger(\omega + \Omega, k) \nabla_k \hat{H}^{\text{diag}} \hat{\Psi}(\omega, k)$, which depends on frequency, $\Omega$, and momentum, $q$, but here the long wavelength limit is taken: $q \to 0$. The superscript “diag” in $\hat{H}^{\text{diag}}$ means that the superconducting order parameter contribution to the thermal current operator has been dropped, which is a very good approximation for Sr$_2$RuO$_4$ since its superconducting gap is much smaller than the normal state band parameters. Then $\kappa_0/T$ can be computed from a thermal Kubo formula. The final result is

$$\frac{\kappa_0(n_i)/T}{\pi^2 k_B^3/3} \equiv \frac{\pi}{2} \sum_k \text{Tr} \left\{ \partial_{k_x} \hat{H}^{\text{diag}}(k) \hat{A}(0, k) \partial_{k_x} \hat{H}^{\text{diag}}(k) \hat{A}(0, k) \right\},$$

where $\hat{A}(\omega, k) \equiv \{ \hat{G}_\text{ret}(\omega, k) - \hat{G}_\text{adv}(\omega, k) \}/(-i 2\pi)$ with the retarded/advanced Green’s function given by $G_{\text{ret/adv}}(\omega, k) = G(i\omega_n \to \omega \pm i\delta, k)$. We normalize $\kappa_0(n_i)/T$ by its value at the critical impurity concentration, $n_{i,c}$ (the corresponding normal impurity scattering rate is denoted as $\Gamma_c$). Since $n_i \ll \Gamma_N$, then $\Gamma_N/\Gamma_c = n_i/n_{i,c}$ and also $\kappa_0(n_i)/\kappa_0(n_{i,c}) = \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)$.

### III. SCTA RESULTS FOR DIFFERENT PAIRING MODELS WITH DEEP MINIMA

#### A. 2-band model

We consider several different chiral $p$-wave pairing models with deep gap minima that are relevant to Sr$_2$RuO$_4$, providing details on each model as well as the corresponding numerical results for the residual thermal conductivity. The first one is a simplified model, the 2$d$-band chiral $p$-wave pairing model proposed in Ref. [21]. In this model only the two quasi-1d $d_{xz}$ and $d_{yz}$ orbitals are considered. The BdG Hamiltonian is

$$\hat{H}_\text{BdG} = \begin{pmatrix} \epsilon_a(k) & g(k) & \Delta_a(k) & 0 \\ g(k) & \epsilon_b(k) & 0 & \Delta_b(k) \\ \Delta_a^\dagger(k) & 0 & -\epsilon_a(k) & -g(k) \\ 0 & \Delta_b^\dagger(k) & -g(k) & -\epsilon_b(k) \end{pmatrix},$$

where $g(k) = -2t \cos k_x - 2t' \cos k_y - \mu$, $\epsilon_a(k) = -2t \cos k_y - 2t' \cos k_x - \mu$, $\epsilon_b(k) = -2t'' \sin k_x \sin k_y$, $\Delta_a(k) = \Delta \sin k_x \cos k_y$, and $\Delta_b(k) = i\Delta \sin k_y \cos k_x$. The band parameters are chosen to be $(t, t', t'', \mu) = (0.1, 0.1, 0.1, 1.0)$ [21,22]. $\Delta$ is the overall superconducting gap magnitude, whose clean system value is left unspecified here since the normalized thermal conductivity $\kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)$ to be calculated does not depend on it. Because of the four-fold rotational crystal symmetry (preserved by our impurity scattering potential), there are only four nonzero independent impurity self energy matrix elements: $\Sigma_{11} = \Sigma_{22}, \Sigma_{12} = \Sigma_{21}, \Sigma_{33} = \Sigma_{44}$, and $\Sigma_{32} = \Sigma_{23}$. All other matrix elements are zero. Solving the coupled equations for these nonzero matrix elements as outlined previously and calculating the thermal conductivity, we obtain the numerical result in Fig. 1, the red $\triangle$ points. Comparing it to the single-band $d$-wave and isotropic chiral $p$-wave pairing results we see that, interestingly, the results of $\kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)$ for $\Gamma_N/\Gamma_c > |\Delta(k)|_{\text{min}}/|\Delta(k)|_{\text{max}} \approx 7\%$ (see Appendix A) Fig. 1 are almost identical to the $d$-wave pairing result and can easily explain the experimental data points except the one at $\Gamma_N/\Gamma_c \approx 5\%$, which is below the gap anisotropy ratio $R$.

If a smaller hybridization parameter $t'' = 0.05t$, defined in $g(k)$ of Eq. (7), is taken as in Ref. 50 then the gap minima in Appendix A Fig. 4 become even deeper with a correspondingly smaller gap anisotropy ratio on the $\beta$ band, $R \approx 3\%$. In this case all the experimental data points in Fig. 1 can be accounted for by the two-band model, as shown in the inset of Fig. 1.

The fact that the agreement between the simple $d$-wave model used in Ref. 28 and the 2-band chiral $p$-wave model for Sr$_2$RuO$_4$ of Ref. 21 with $\Gamma_N > \Delta_{\text{min}}$ is surprisingly good with no adjustment of parameters merits some explanation. It can be understood from the asymptotic expression of the residual thermal conductivity

$$\lim_{\Gamma_N \to 0} \frac{\kappa_0(\Gamma_N)}{\kappa_0(\Gamma_c)} = \frac{2}{L_{\text{PS}}} \sum_i \frac{\Gamma_c}{v^2_\Delta},$$

where we have used $\lim_{\Gamma_N \to 0} \kappa_0(\Gamma_N)/(\pi^2 k_B^2 T/3) = (1/4\pi^2) \sum_i v_F/v^2_\Delta$ and $\kappa_0(\Gamma_c)/(\pi^2 k_B^2 T/3) = (L_{\text{PS}} v_F/8\pi^2)/T_c$ for a 2$d$ single-band superconductor with a circular FS and isotropic Fermi velocity.
The sum of the right hand side of Eq. (8); while both minima (see Appendix A Fig. 4) and contributes to the number of near-nodes on the FS, with that of the single-band chiral $\Delta$-wave model with a smaller orbital $\Delta$-wave pairing model with an isotropic FS[35]. The gap structure on the FS is the 2-band chiral $p$-wave model from Ref. 26 that was used to explain the absence of observable edge currents [23,26]. Following Ref. 26 we choose the normal state part of $\hat{H}_{SBG}$ to be identical to that from Refs. 24 and 26. Following Ref. 26 we choose the superconducting order parameter matrix in the three orbital basis of $d_{xz},d_{yz}$ and $d_{xy}$ to be $\Delta_{\alpha,\beta} = \Delta_\alpha \delta_{\alpha,\beta}$, where $\Delta_\alpha$ for each orbital is a linear combination of different harmonics consistent with chiral $p$-wave pairing on a square lattice:

$$
\begin{pmatrix}
\Delta_{xz} \\
\Delta_{yz} \\
\Delta_{xy}
\end{pmatrix} = \begin{pmatrix}
\Delta_{x} \\
\Delta_{y} \\
\Delta_{z}
\end{pmatrix} = \begin{pmatrix}
a_1 & a_2 & a_3 \\
b_1 & b_2 & b_3
\end{pmatrix} \begin{pmatrix}
g_1' \\
g_2' \\
g_3'
\end{pmatrix} + i \begin{pmatrix}
a_1 & a_2 & a_3 \\
b_1 & b_2 & b_3
\end{pmatrix} \begin{pmatrix}
g_1'' \\
g_2'' \\
g_3''
\end{pmatrix}
$$

where

$$
\begin{align}
(g_1', g_2', g_3') &= (\sin k_x, \sin k_y \cos k_y, \sin 3k_x) \\
(g_1'', g_2'', g_3'') &= (\sin k_y, \sin k_y \cos k_x, \sin 3k_y)
\end{align}
$$

B. 2d 3-band model

The second chiral $p$-wave pairing model we consider is the 2d 3-band pairing model from Ref. 26 that was used to model the results of a weak-coupling RG calculation[25]. The gap structure on the $\alpha$ and $\beta$ bands is similar to the 2-band model of Sec. IIIA with 8 near-nodes on the $\beta$ band. This model fits critical specific heat jump data[23] and has been used to explain the absence of observable edge current[26].
Based on Ref. [20] we choose the six coefficients \((a_1, a_2, a_3, b_1, b_2, b_3) = (0.067, 0.33, 0.18, 0.15, -0.3)\) such that the gap functions on each band, obtained from \(\Delta_{x^2-y^2}, \Delta_{py}\) and \(\Delta_{y^2}\) by unitary transformation, fit the weak coupling RG-calculation results well[23]. This coefficient combination produces a ratio of the gap magnitude on \(\alpha, \beta\) bands to that on \(\gamma\) band about 1/2, which predicts a critical specific heat jump comparable to the experimental value. However, the pairing gap function obtained gives a result of \(\Delta_{x^2-y^2}/\Delta_{py}\) quite different from that of the \(d\)-wave case (see Appendix [A] Fig. [7]) for two reasons:

1. The \(\Delta_{x^2-y^2}/\Delta_{py}\) calculated, given in Fig. [7] of Appendix [A] has a multi-gap structure. There is a peak at \(\Gamma_N/\Gamma_c \approx 0.25\), which, however, is absent in the single band \(d\)-wave result and also not observed in Sr2RuO4 measurement. That peak is a result of the \(\alpha, \beta\) bands becoming normal, while the \(\gamma\) band remains superconducting at \(\Gamma_N/\Gamma_c \gtrsim 0.25\) (see Appendix [A] for further discussions).

A more realistic model would include inter-band Cooper pair scattering that ensures a single \(\gamma\) for the three bands and, if sufficiently strong, may eliminate the peak at \(\Gamma_N/\Gamma_c \approx 0.25\). Here we avoid the multi-gap structure by simply adjusting the gap magnitude on each band so that the superconductivity on all three bands are destroyed at the same \(\Gamma_N\). In other words, we impose a constraint on the gap magnitude ratio among different bands. However, this constraint would likely be modified in the presence of inter-band interactions that are neglected in our model.

2. Even if the gap magnitude ratio is adjusted such that the multi-gap structure disappears, the obtained limit \(\lim_{\Gamma_N \to 0} \Delta_{x^2-y^2}/\Delta_{py}\) value, when the deep minima are treated as accidental nodes, is still smaller than that of \(d\)-wave (see Appendix [A] Fig. [7]), which is about 26. This is not surprising since the \(\alpha, \beta\) bands alone would give approximately the \(d\)-wave value and the \(\gamma\) band gap, while anisotropic, does not have near-nodes. From Eq. [8] we see that we need to either decrease the gap function slope near deep minima or increase the number of deep minima. This is a serious constraint that the experimental data places on chiral \(p\)-wave models with deep gap minima only on the \(\alpha, \beta\) bands and not on the \(\gamma\) band.

In Appendix [A] we show that the 3-band model with a reduced \(\Delta_{py}\) at the 8 near-nodes of the \(\beta\) band agrees with the experimental data. However, since the \(\Delta_{py}\) is noticeably smaller than expected for Sr2RuO4, it is useful to consider other ways one might reconcile 3-band chiral \(p\)-wave models with the residual thermal conductivity data. Models with horizontal nodes and with deeper minima on the \(\gamma\) band are considered below.

C. 3d 3-band model with horizontal line nodes

Horizontal line nodes in a 3d pairing model is one possibility for reconciling chiral \(p\)-wave with the residual thermal conductivity data. Because of the highly quasi-2d nature of Sr2RuO4, which implies weak inter-layer coupling, pairing with a strong \(k_z\) dependence and, therefore, horizontal line nodes may seem unlikely, particularly on the \(\gamma\) band which has the weakest interlayer coupling. However, chiral \(p\)-wave pairing models with either a \(\cos k_x/2\) or \(a + b \cos k_x\) dependence on \(k_x\) (usually just on the \(\alpha, \beta\) bands) being proposed to explain some experiment[23,24]. Here \(a, b\) are two coefficients. Note that higher order harmonics in \(k_z\) in the gap function are more unlikely given the weak \(k_z\) dependence of all three bands.

We can estimate the horizontal line node contribution to the residual thermal conductivity ratio using an analysis similar to that used to obtain Eq. [3], together with values for the average Fermi velocities and lengths of Fermi surface in the \(ab\)-plane. Assuming horizontal line nodes on both the \(\alpha, \beta\) bands at one or more values of \(k_z\) we obtain

\[
\frac{\kappa(\Gamma_N)}{\kappa(\Gamma_c)} \approx 0.23 \sum_{i \Delta} \frac{\Gamma_c}{v_{x,y,i}^{26}}.
\]  

(11)

where \(i\) is summed over the values of \(k_z\) corresponding to horizontal nodes, \(v_{x,y,i}^{26}\) is the gap function velocity averaged over the horizontal line nodes of both the \(\alpha, \beta\) bands, and we have restored the lattice spacing constant \(c\) to make the expression explicitly dimensionless. The superscript “c” in \(v_{x,y,i}^{26}\) indicates that the gap velocity is along the \(c\)-direction axis. The case of accidental horizontal nodes (i. e., not protected by symmetry) can be modelled by a gap function \(\Delta(k_z) = \Delta(a + b \cos k_z)/(|a| + |b|)\), where \(\Delta\) should be understood as the gap magnitude averaged over the in-plane FS contours of both the \(\alpha, \beta\) bands and \(|a| < |b|\). In this case, from Eq. (11) and using \(\Gamma_c/\Delta = \sqrt{c}/4\) as a rough estimate[20], one finds

\[
\frac{\kappa(\Gamma_N)}{\kappa(\Gamma_c)} \approx 0.19 \frac{|b|/|a| + 1}{\sqrt{|b/a|^2 - 1}}.
\]  

(12)

It follows that one could fit the experimental residual thermal conductivity with horizontal line nodes alone (without vertical nodes) if \(b/a \sim 3.3\), and we have confirmed this with a numerical calculation of \(\kappa(\Gamma_N)/\kappa(\Gamma_c)\).

From the above analysis, it is clear that models with both deep vertical minima and horizontal nodes on the \(\alpha, \beta\) bands[20,21] may be compatible with the experimental data depending on the details of these models. It follows from Eq. (12) and our previous numerical results (Appendix [A] Fig. [7]) that adding \(a + b \cos k_z\) with \(b > a\) to the \(\alpha, \beta\) band pairing gap functions in Eq. [9] and using the same coefficients in Eq. [9] as in Ref. [23] and [20] leads to a limit \(\lim_{\Gamma_N \to 0} \kappa(\Gamma_N)/\kappa(\Gamma_c)\) value larger than that of the single-band \(d\)-wave. The minimum of
$$\lim_{\Gamma_N \to 0} \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)$$ is achieved when \( a = 0 \), which can be modelled by making the following replacement in Eq. [9]

$$\{g^1_x, g^2_x, g^1_y, g^2_y\} \rightarrow \{g^1_x, g^2_x, g^1_y, g^2_y\} \times \cos k_z. \quad (13)$$

However, even in this case, we will need to reduce \( v_\Delta \) at the vertical deep minima slightly to fit the experimental data. Fig. 1 (dark-green \( \times \)) shows the residual thermal conductivity for this model with both horizontal nodes and vertical near-nodes with parameters

$$\begin{align*}
(a_1, a_2, b_1, b_2, b_3) &= (-0.1, 0.75, 2.0, 0.18, 0.15, -0.3).
\end{align*}$$

Details of the gap function are given in Appendix A and, as before, the relative gap magnitudes of different bands have been tuned to vanish at the same impurity concentration. Note, to explain the data with this model puts constraints on both the horizontal and vertical nodes or near-nodes. Also, note that using \( \cos k_z/2 \) in Eq. (13) is as good as \( \cos k_z \), as can be seen from the previous estimates.

### D. 3-band model with deep minima on the \( \gamma \) band

While weak coupling RG calculations for \( \text{Sr}_2\text{RuO}_4 \) predict substantial anisotropy on the \( \gamma \) band, the ratio of minimum to maximum gap on the \( \gamma \) band is predicted to be only 25%. However, functional RG (fRG) studies\(^{22}\) found this ratio to be about 10%. The deeper minima along the \( k_z \) and \( k_y \) axes may result from the fact that fRG mixes in states away from the FS and closer to the Brillouin zone boundary where the chiral \( p \)-wave gap must vanish by symmetry. However, this calculation also found much weaker superconductivity on the \( \alpha/\beta \) bands, an effect that may be modified if spin orbital coupling were to be included. In any case, the 3-band functional RG results would give a poor fit to the experimental thermal conductivity data because the superconductivity on the \( \alpha/\beta \) bands is about an order of magnitude smaller than on the \( \gamma \) band. Here, we combine the fRG results for the \( \gamma \) band with the simple model used in Sec. IIIA for the \( \alpha/\beta \) bands.

The BdG Hamiltonian of the combined 3-band model is

$$\hat{H}_{\text{BdG}} = \begin{pmatrix}
\epsilon_a & g & 0 & \Delta_a & 0 & 0 \\
g & \epsilon_b & 0 & 0 & \Delta_b & 0 \\
0 & 0 & \epsilon_c & 0 & 0 & \Delta_c \\
\Delta_a^* & 0 & -\epsilon_a & -g & 0 & 0 \\
0 & \Delta_b^* & 0 & -g & -\epsilon_b & 0 \\
0 & 0 & \Delta_c^* & 0 & 0 & -\epsilon_c
\end{pmatrix}, \quad (14)$$

where for brevity we have suppressed the \( k \) dependence of all matrix elements. The definitions of \( \epsilon_a(k), \epsilon_b(k), g(k), \Delta_a(k) \) and \( \Delta_b(k) \) are identical to those given for Eq. 7, except that the smaller orbital hybridization \( t' = 0.05t \) has been adopted here. \( \epsilon_c(k) = -2t' \cos k_x + \cos k_y - 4t'' \cos k_x \cos k_y - \mu_c \), with \((t', t'', \mu_c) = (0.8, 0.35, 1.3)\), is the \( \gamma \) band normal state energy dispersion, taken from Ref. 22. The \( \gamma \) band gap of Ref. 22 can be approximated by

$$\Delta_{\gamma}(k) = b_1(g^1_x + ig^2_y) + b_2(g^1_y + ig^2_y) + b_3(g^1_x + ig^2_x),$$

where \( \{g^1_x, g^2_x, g^1_y, g^2_y\} \) are defined in Eq. (10) and we choose the three coefficients to be \((b_1, b_2, b_3) = (-0.9, 1, 0.25)\). This functional form of \( \Delta_{\gamma}(k) \) gives an angular dependence of the \( \gamma \) band gap function similar to the fRG results. In particular, the gap anisotropy ratio, \( R = \Delta_{\text{min}}/\Delta_{\text{max}} \approx 10\% \), and the gap function slope near the deep minima on the \( \gamma \) band FS, which are the two important things for the residual thermal conductivity at small impurity scattering rate, are almost the same as in Ref. 22.

The numerical results of \( \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c) \) are shown in Fig. 3 by the black \( \Delta \). Although the experimental data at \( \Gamma_N/\Gamma_c \geq 15\% \) can be accounted for by the combined 3-band within experimental error bars, the gap anisotropy ratio \( R \) would need to be decreased such that \( R \lesssim 5\% \) to be consistent with the experimental data point at \( \Gamma_N/\Gamma_c \approx 5\% \) (assuming \( v_\Delta \) and \( v_F \) near the minima remain the same). Therefore, the experimental data imposes quite severe constraints on the 3-band model in the absence of horizontal nodes.

### IV. SELF-CONSISTENT BDG ANALYSIS

#### A. Model and parameters

To study the nature of the low-energy states beyond the SCTA, including order parameter inhomogeneity, we self-consistently solve the real-space BdG equations in the presence of dilute unitary impurities. We focus on the 2-band chiral \( p \)-wave pairing model with deep minima from Ref. 21 described in Sec. IIII. The BdG Hamiltonian for the case where \( k \) is a good quantum number is given by Eq. 7. In this section, we work in real space, where the BdG Hamiltonian on a square lattice is

$$H = - \sum_{i,j,\alpha,\beta} \left[ t_{\alpha \beta} \hat{c}_{i\alpha \sigma}^\dagger \hat{c}_{j\beta \sigma} + \text{h.c.} \right] - \sum_{i,\alpha,\sigma} \mu_i \hat{c}_{i\alpha \sigma}^\dagger \hat{c}_{i\alpha \sigma} + \sum_{i,\alpha,\sigma} \left[ \Delta_{\alpha}^0 \hat{c}_{i\alpha \sigma}^\dagger \hat{c}_{i\sigma} + \text{h.c.} \right], \quad (15)$$

where \( c_{i\alpha \sigma} \) is the electron annihilation operator for site \( i \). As before, the orbital labels are \( \alpha = a \) or \( b \) (for \( d_{xz} \) or \( d_{yz} \) orbitals). The model of Ref. 21 includes only nearest-neighbour and next-nearest-neighbour hopping and next-nearest neighbour hopping. The nonzero hopping matrix elements are \( t_{i,i+x}^{aa} = t_{i,i+y}^{bb} = t_{i,i+x}^{ab} = t_{i,i+y}^{ba} = t_{i,i+x}^{\alpha} = t_{i,i+y}^{\beta} = t_{i,i+x}^{\gamma} = t_{i,i+y}^{\delta} = t' \), where \((t, t', t'') = (1.0, 0.1, 0.1)\). In the absence of disorder, the chemical potential \( \mu_i = 1 \). In this model, the chiral \( p \)-wave pairing order parameter is \( \Delta_{aa}^{i,x+y+\hat{y},\sigma} = -i \Delta_a \) (with \( \Delta_{aa}^{i,x+y+\hat{y},\sigma} = +i \Delta_a \)) and \( \Delta_{bb}^{i,x+y+\hat{y},\sigma} = +\Delta_b \) (with \( \Delta_{bb}^{i,x+y+\hat{y},\sigma} = -\Delta_b \)) with all other \( \Delta_{ij,\sigma} \) = 0 and no inter-orbital pairing. Here \( \sigma = -\sigma \) and we choose the spin quantization axis such that the spin part of the
superconducting order parameter is in the triplet state \( \uparrow \downarrow + \downarrow \uparrow \). \( \Delta_\alpha \) and \( \Delta_\beta \) are functions of \( i \) and \( \delta = \pm \hat{x} \pm \hat{y} \) in the presence of disorder. In the uniform case this choice of pairing results in the chiral p-wave gap structure

\[
\Delta(k) \approx 4 \left[ \Delta_\alpha \sin(k_x)\cos(k_y) + i\Delta_\beta \sin(k_y)\cos(k_x) \right],
\]

whose real and imaginary parts correspond to \( \Delta_\alpha(k) \) and \( \Delta_\beta(k) \) of Eq. (7).

The BdG equations are solved together with the self-consistent gap equation

\[
\Delta_{\alpha}(i, \delta) = \frac{V}{2} \sum_{n=1}^{2N_x N_y} \left\{ u_{n\alpha}(i) u_{n\alpha}^*(i + \delta) - u_{n\alpha}(i + \delta) v_{n\alpha}^*(i) \right\} [1 - 2f_n]
\]

where \( \alpha = \{a, b\}, f_n \equiv [1 + e^{E_n/T}]^{-1}. V \) is the attractive interaction strength and we use \( V = 2.5t \). \( N_x \times N_y \) is the square lattice size. \( (u_{n\alpha}(i), u_{n\beta}(i); v_{n\alpha}(i), v_{n\beta}(i)) \) is the \( n \)-th Bogoliubov quasiparticle wavefunction that diagonalizes the BdG Hamiltonian, with corresponding eigenvalue \( E_n \), i.e.,

\[
c_{i\alpha\sigma} = \sum_{n=1}^{2N_x N_y} \left[ u_{n\alpha}(i) \gamma_{n\sigma} + v_{n\alpha}^*(i) \gamma_{n\sigma}^\dagger \right],
\]

where \( \gamma_{n\sigma} \) is the Bogoliubov quasiparticle annihilation operator.

We study the effect of dilute unitary scattering disorder through an on-site chemical potential term of strength \( V^\text{imp} \) which is isotropic and diagonal in the orbitals. \( V^\text{imp} = 100t \) has been chosen for the unitary scattering limit. In the presence of disorder, the chemical potential is tuned such that the electron density \( \langle n \rangle \approx 2.6 \) per site remains the same as that of the uniform and clean system with \( \mu_t \equiv 1 \). For each disorder configuration we solve the BdG and gap equations self-consistently until the variational free energy, order parameter, and electron density are converged to within \( \epsilon = 10^{-4} \). At least ten disorder configurations are averaged over for the largest system sizes studied, \( N_x = N_y = 100 \), but the results do not qualitatively change for smaller systems, \( N_x = N_y \leq 40 \), with over 200 disorder configurations.

For clean system and with the above choice of parameters, the self-consistent gap in the band limit at \( T = 0 \) is \( \Delta_\alpha = \Delta_\beta = 0.274 \) with \( \max\{\Delta_\beta(k)\} = 0.06, \min\{\Delta_\alpha(k)\} = 0.41 \) and max \( \{\Delta_\alpha(k)\} = 1 \) over the \( \alpha - \) and \( \beta \)-sheets of Fermi surface (see Appendix A Fig. 4). Note, in order to reduce finite size effects in our numerical BdG calculations, we have chosen a pairing interaction strength that corresponds to rather strong coupling, with a large gap. Consequently, the density of impurities at \( \Gamma_c \) for our model is noticeably larger than that expected for \( \text{Sr}_2\text{RuO}_4 \). However, other than changing the scale for disorder, this does not impact the low temperature results that we show in this section.

To make a comparison with the experiment in Ref. [28] where the impurity scattering rate for the sample studied is estimated to be \( \Gamma_N/\Gamma_c \approx 0.26 \), we need to estimate what impurity concentration, \( n_\text{exp} \), that scattering rate corresponds to in our BdG calculation. This can be done by using \( n_\text{exp}/n_c = \Gamma_N/\Gamma_c \), where \( n_c \) is the impurity density at which the disorder averaged order parameter vanishes. For the parameters we have chosen, \( n_c \approx 42\% \), which implies \( n_\text{exp} \approx 11\% \). Also, since our T-matrix calculation shows that the behavior of \( \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c) \) is quite different depending on whether \( \Gamma_N/\Gamma_c \lesssim R \) or \( \Gamma_N/\Gamma_c \gtrsim R \), where \( R = \Delta_{\text{min}}/\Delta_{\text{max}} \approx 7\% \) (see Appendix A Fig. 7), we focus on impurity concentrations around the value \( n_t^* \approx 3\% \) at which \( n_t^*/n_c = \Gamma_N/\Gamma_c = R \).

### B. Inverse participation ratio

The SCTA shows substantial residual thermal conductivity, implying that the low-energy states become delocalized, for scattering rates \( \Gamma_N/\Gamma_c \gtrsim \Delta_{\text{min}}/\Delta_{\text{max}} \) (for further discussions, see Appendix B). Here we study the localized or non-localized nature of the low-lying states with varying disorder within self-consistent BdG, by computing the inverse participation ratio (IPR) \( A_n \) given by \[ A_n = \frac{\langle |u_{n\alpha}|^4 \rangle + \langle |v_{n\alpha}|^4 \rangle}{\left[ \langle |u_{n\alpha}|^2 \rangle + \langle |v_{n\alpha}|^2 \rangle \right]^2}, \]
\[
\kappa(T) = \frac{1}{T} \lim_{\omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \langle \text{Im} \, \Lambda_{xx}(q, \Omega + i\delta) \rangle,
\]

where \(\Lambda_{xx}\) is the \(xx\)-component of the thermal current-current correlation function tensor for a given disorder configuration and \(\langle \cdots \rangle\) denotes an average over different configurations. Details of the calculation can be found in Appendix D. We show the numerical results in Fig. 3 for two impurity concentrations: \(n_{\text{exp}} \approx 11\%\), which corresponds to \(\Gamma_N/\Gamma_c \approx 0.26\) from the experiment, and the critical concentration \(n_c \approx 42\%\). Quantities are plotted as a function of temperature relative to the clean transition temperature, \(T_{c,0} \approx 0.43\). The blue circles correspond to the disorder and spatially averaged gap \(\langle \Delta \rangle\) scaled to its zero temperature value \((\Delta(T = 0))\) for \(n_{\text{exp}} = 11\%\), which shows that the superconducting-to-normal transition occurs at \(T_c/T_{c,0} \approx 0.8\). Note that the transition is significantly broadened by disorder.

\[\kappa(T) \approx \frac{1}{T} \lim_{\omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \langle \text{Im} \, \Lambda_{xx}(q, \Omega + i\delta) \rangle,\]

In Fig. 3, the IPR, \(A_n\), averaged over states \(n\) with \(E_n \leq \Delta_{\text{min}}\), is plotted versus \(1/L^2\). For the concentration \(n_i = 0.5\% < n_s^* \approx 3\%,\) the IPR extrapolates to a value corresponding to \(\xi_L \approx 70\) lattice sites, whereas for concentrations \(n_i > n_s^*\), the IPR shows linear scaling with an extracted localization length greater than the largest system size studied. This shows that for \(n_i \gtrsim n_s^*\), or equivalently \(\Gamma_N/\Gamma_c \gtrsim \Delta_{\text{min}}/\Delta_{\text{max}}\), the states near zero energy are delocalized and can make contributions to the thermal transport, which supports our conclusion extracted from SCTA calculations on the residual thermal transport in Sec. II. The existence of a threshold impurity concentration value, \(n_s^*\), for sub-gap-minima states to be delocalized in the presence of deep gap minima should be contrasted with the \(d\)-wave case. In that case the impurity-induced states mix with extended states and thereby contribute to the thermal transport even with an infinitesimal amount of disorder, since the clean system has extended states all the way down to zero energy.

\[\kappa(T) \approx \frac{1}{T} \lim_{\omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \langle \text{Im} \, \Lambda_{xx}(q, \Omega + i\delta) \rangle,\]

C. Thermal Conductivity in BdG

The longitudinal thermal conductivity can be computed from the Kubo formula

\[\kappa(T) = \frac{1}{T} \lim_{\omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \langle \text{Im} \, \Lambda_{xx}(q, \Omega + i\delta) \rangle,\]

where \(\Lambda_{xx}\) is the \(xx\)-component of the thermal current-current correlation function tensor for a given disorder configuration and \(\langle \cdots \rangle\) denotes an average over different configurations. Details of the calculation can be found in Appendix D. We show the numerical results in Fig. 3 for two impurity concentrations: \(n_{\text{exp}} \approx 11\%\), which corresponds to \(\Gamma_N/\Gamma_c \approx 0.26\) from the experiment, and the critical concentration \(n_c \approx 42\%\). Quantities are plotted as a function of temperature relative to the clean transition temperature, \(T_{c,0} \approx 0.43\). The blue circles correspond to the disorder and spatially averaged gap \(\langle \Delta \rangle\) scaled to its zero temperature value \((\Delta(T = 0))\) for \(n_{\text{exp}} = 11\%\), which shows that the superconducting-to-normal transition occurs at \(T_c/T_{c,0} \approx 0.8\). Note that the transition is significantly broadened by disorder.

\[\kappa(T) \approx \frac{1}{T} \lim_{\omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \langle \text{Im} \, \Lambda_{xx}(q, \Omega + i\delta) \rangle,\]

In Fig. 3, the IPR, \(A_n\), averaged over states \(n\) with \(E_n \leq \Delta_{\text{min}}\), is plotted versus \(1/L^2\). For the concentration \(n_i = 0.5\% < n_s^* \approx 3\%,\) the IPR extrapolates to a value corresponding to \(\xi_L \approx 70\) lattice sites, whereas for concentrations \(n_i > n_s^*\), the IPR shows linear scaling with an extracted localization length greater than the largest system size studied. This shows that for \(n_i \gtrsim n_s^*\), or equivalently \(\Gamma_N/\Gamma_c \gtrsim \Delta_{\text{min}}/\Delta_{\text{max}}\), the states near zero energy are delocalized and can make contributions to the thermal transport, which supports our conclusion extracted from SCTA calculations on the residual thermal transport in Sec. II. The existence of a threshold impurity concentration value, \(n_s^*\), for sub-gap-minima states to be delocalized in the presence of deep gap minima should be contrasted with the \(d\)-wave case. In that case the impurity-induced states mix with extended states and thereby contribute to the thermal transport even with an infinitesimal amount of disorder, since the clean system has extended states all the way down to zero energy.
for Sr$_2$RuO$_4$. First, in order to account for all the experimental residual thermal conductivity data points in Fig. 1, the gap minima need to be sufficiently deep such that the gap anisotropy ratio satisfies $R \lesssim 5\%$.

However, this condition can have some caveats since the experimental data points of Fig. 1 were obtained by assuming samples with $T_{c0} = 1.5$K are in the true clean limit, while a recent experimental study suggests that this might not be the case. If the $\Gamma_N/T_c$ for the cleanest sample in Fig. 1 is higher than 5%, the condition $R \lesssim 5\%$ would be modified to a less-severe constraint. Second, if there are no horizontal nodes, it is particularly difficult to reconcile chiral-$p$-wave order with residual thermal conductivity data. While there are arguments for the possible existence of near-nodes on the $\alpha$ and $\beta$ bands, no similar arguments exist for the gap on the $\gamma$ band. Weak-coupling calculations that include spin orbital coupling do predict minima along the $(1,1)$ direction of the $ab$-plane for the gap on the $\gamma$ band, but these are not particularly deep.

On the other hand, minima along the $k_z$ or $k_y$ axes are expected by symmetry, but one would only expect these to be extremely deep if the FS was extremely close to the zone boundary, in which case the contribution to the residual conductivity would become too small to explain the experimental data because of the reduced $v_F$ near the zone boundary. We note that for vertical near-nodes along or near the $(1,1)$ direction, such as those on the $\alpha$ and $\beta$ bands, such anisotropy of $v_F$ is not a concern because they are far away from the zone boundary.

The experimental data might be more easily accounted for by a 3$d$ 3-band chiral $p$-wave model with accidental horizontal line nodes or with a coexistence of vertical near-nodes and horizontal line nodes. However, constraints exist even in such a model. In the absence of horizontal nodes on the $\gamma$ band, if two horizontal nodes exist on each of the $\alpha$ and $\beta$ bands alone without vertical near-nodes or other horizontal nodes, the gap velocity $v_\Delta$ at the horizontal nodes needs to be about $1/3$ of that of simple $d$-wave to compensate for the absence of horizontal nodes on the $\gamma$ band; when accidental horizontal nodes on the $\alpha$ and $\beta$ bands coexist with vertical near-nodes, the $v_\Delta$ at the horizontal nodes needs to be about $1/2$ of that of $d$-wave, depending on the $v_\Delta$ near the vertical near-nodes. We note that a recent 3$d$ weak-coupling RG calculation of the single-band repulsive Hubbard model found chiral $p$-wave order with horizontal line nodes even when the FS is a fairly weakly corrugated cylinder in the low electron density limit. A similar 3$d$ calculation for Sr$_2$RuO$_4$, including all three bands and the $k_z$ dependence of the spin-orbital coupling would be very helpful to see how favorable horizontal nodal gap structures are.

Lastly, we comment on some aspects of the thermal transport experiment that we have left out in this study. First, while we do not include magnetic fields in this paper, we expect that the residual thermal conductivity data at finite but small magnetic fields can be understood similarly as it only relies on quasiparticles excited near deep gap minima by the fields. Second, the $c$-axis thermal transport also places considerable constraints on chiral $p$-wave models as the analysis in Ref. 28 suggests that nodes or near-nodes need to be present on all 3 bands. This also emphasizes the importance of realistic microscopic 3$d$ calculations for Sr$_2$RuO$_4$.

**Note added:** Recently, a 3-band fRG calculation, which takes into account the spin-orbital coupling and finds extremely deep gap minima on the $\gamma$ band, has been reported by Wang et al. They have calculated the thermal conductivity at a finite temperature $T = T_c/30$ and compared the result to the experimental residual thermal conductivity data, which is, however, obtained by extrapolating the finite $T$ data to $T = 0$. Therefore, the quantity to be compared with the experiments should be the one at $T = 0$. Were the $T = 0$ thermal conductivity used to compare with the experiments in Ref. 59, the agreement would be poor at the smaller impurity scattering rates.

**VI. ACKNOWLEDGMENTS**

W.), and the Department of Energy, Office of Basic Energy Sciences, under contract No. DE-AC02-76SF00515 (J. F. D.) at Stanford. This work was made possible by the facilities of the Shared Hierarchical Academic Research Computing Network (SHARCNET:www.sharcnet.ca) and Compute/Calcul Canada.

**Appendix A: Gap function profiles and residual thermal conductivity**

In this Appendix we show the gap function profiles of the chiral $p$-wave models used in Fig. 1 along the Fermi surface contours in the $k_x - k_y$ plane. Fig. 4 is for the 2-band model, defined in Eq. (7), and Fig. 5 is for the 3$d$ 3-band model (defined in Eq. (13)) in the $k_z = 0$ plane. Fig. 6 shows a modified 2$d$ 3-band gap function profile that is discussed below.

From Fig. 5 we see that the overall gap function profiles of our 3$d$ 3-band pairing model at $k_z = 0$ are similar to those from Refs. 23 and 26. This model supports horizontal line nodes at $k_z = \pm \pi/2$, which add a considerable contribution to the residual thermal conductivity and compensate for the fact that there are no deep vertical minima on the $\gamma$ band.

Fig. 7 shows the $\kappa_0(\Gamma_N)/T$ calculated within the SCTA for the 2$d$ 3-band pairing model defined in Eq. (9). The blue filled circle is obtained by using the gap parameters from Refs. 23 and 26. The $\Gamma_N$ dependence of
\[ \Delta(\phi_k) \] of the 2-band model on the \( \alpha \) and \( \beta \) FS sheets in the first quadrant of the 2d Brillouin zone. \( \phi_k \) is the azimuthal angle of Fermi wavevectors on each band and its definition can be found in the inset of Fig. 6. The top red and bottom dark-green solid lines are for the \( \alpha \) and \( \beta \) bands, respectively, obtained with the orbital hybridization parameter \( t'' = 0.1 t \) (see Eq. (13) for the definitions of \( t \) and \( t'' \)). For this parameter choice the gap anisotropy ratio on the \( \beta \) band is \( R = \Delta_{\min}/\Delta_{\max} \approx 7\% \). Also shown is the \( \beta \) band gap function profile (bottom blue dotted line) with a smaller \( t'' = 0.05 t \), for which \( R \approx 3\% \).

\[ \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c) \] in Fig. 7 is quite different from that of the single-band \( d \)-wave because of the peak near \( \Gamma_N/\Gamma_c \approx 0.25 \), which comes from the \( \alpha \) and \( \beta \) bands becoming normal while the \( \gamma \) band remains superconducting at \( \Gamma_N/\Gamma_c \gtrsim 0.25 \).

In our calculation, the \( \alpha \) and \( \beta \) bands are coupled and undergo the superconducting-to-normal transition at the same critical impurity concentration, \( n_i^{\alpha,\beta} \); on the other hand, the \( \gamma \) band is almost uncoupled to the \( \alpha \) and \( \beta \) bands and undergoes the superconducting-to-normal transition at a different \( n_i \). The curvature of the \( \Gamma_N/\Gamma_c \) vs. \( \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c) \) curve in Fig. 7 is due to the coupling between the \( \alpha \) and \( \beta \) bands, which is the main effect on \( \Gamma_N/\Gamma_c \) as \( \kappa_0(\Gamma_N)/\kappa_0(\Gamma_c) \) increases.
bands, and therefore has a different critical impurity concentration, \(n^c\). The values of \(n^{c,\alpha}\) and \(n^{c,\beta}\) are determined by \(N_F = n_F/(\pi N_F) \sim T_c \propto \Delta\) for each band, where \(N_F\) is the corresponding normal state density of states at Fermi energy. This leads to \(n^{c,\alpha}/n^{c,\beta} \approx (N^\alpha_F/N^\beta_F) (\Delta^\alpha/\Delta^\beta) \approx 0.25\), where we have used, in determining \(n^{c,\alpha}/n^{c,\beta}\), that the \(\beta\) band dominates because it has a larger density of states, \(N^\beta_F/N^\alpha_F \approx 0.63\) and \(\Delta^\beta/\Delta^\alpha \approx 0.4\) in the chiral p-wave model of Ref. 23 (see Fig. 4(a) there). This explains why a peak occurs at \(\Gamma_N/\Gamma_c \approx 0.25\) in Fig. 7.

Similar multi-gap structures in specific heat, London penetration depth, and thermal conductivity as a function of temperature have been predicted before, such as in Refs. 60, 66. However, neither those predictions nor the peak at \(\Gamma_N/\Gamma_c \approx 0.25\) in Fig. 7 have been observed in experiments 14,18,28,32. We choose to reduce \(\Delta\) by \(\hat{\Sigma} = 44\) to \(\Delta\) by \(\hat{\Sigma} = 11\) for \(\alpha,\beta\) and \(\gamma\) bands and not on the \(\kappa\) band.

To eliminate the multi-gap structure we simply adjust the relative gap magnitudes among different bands such that they vanish at the same \(\Gamma_N\) but keep the angular dependence of the gap functions on each band the same as in Refs. 23 and 26. The calculated \(\kappa_0(\Gamma_N)/T\) is shown in Fig. 7 by the red \(\Delta\). We see that, similar to the results presented in Fig. 1, the \(\kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)\) appears to saturate to a nonzero constant as \(\Gamma_N/\Gamma_c \to 0\), provided that \(\Gamma_N/\Gamma_c \gtrsim \Delta_{\text{min}}/\Delta_{\text{max}}\). However, that constant is only about 1/2 of that of \(d\)-wave. From Eq. 4 we see that, in order to increase the value of \(\Gamma_N/\Gamma_c \to 0\), we need either increase the number of near-nodes or decrease the gap slope \(u_m\) at each near-node by about 1/2. This puts a strong constraint on the possible gap function profiles in pairing models with the near-nodes existing only on the \(\alpha\) and \(\beta\) bands and not on the \(\gamma\) band.

We choose to reduce \(u_m\) by about 1/2 by choosing the six coefficients in Eq. (4) to be \((a_1, a_2, a_3, b_1, b_2, b_3) \times (-0.8, 0.4, 1.6, 0.18, 0.15, -0.3)\). As a consequence of the simple parameterization we are using, the near-nodes on the \(\beta\) band (which are actually accidental gap nodes for the chosen parameter) are inevitably shifted away from the zone diagonal (see Fig. 6). We adjust the magnitudes of the gap functions in the band basis such that the superconductivity on all three bands vanishes at the same \(\Gamma_N\). Using the gap functions obtained in this way, we calculate the impurity self-energy matrix \(\Sigma\) and residual thermal conductivity, following the procedure that we outlined in Sec. II of the main text. Due to the four-fold rotational symmetry between \(d_{xz}\) and \(d_{yz}\) orbitals, the impurity self-energy matrix elements satisfy: \(\Sigma_{11} = \Sigma_{22}, \Sigma_{33} = \Sigma_{21}, \Sigma_{44} = \Sigma_{55}, \Sigma_{45} = \Sigma_{54}\). All other matrix elements are zero except \(\Sigma_{33}\) and \(\Sigma_{46}\) because of the orthogonality between \(\{d_{xz}, d_{yz}\}\) and \(d_{xy}\) orbitals. The numerical result of \(\kappa_0/T\) is given in Fig. 7 by the purple x points. We see that they are similar to the \(d\)-wave results and can account for the experimental data. However, this fit did require a \(u_m\) that is significantly smaller than the weak coupling RG results predict and is unlikely to be realized in Sr$_2$RuO$_4$.

**Appendix B: Localization effects on the residual thermal conductivity within SCTA**

Although, in the SCTA method, the translational invariance is restored in real-space after impurity-averaging, which seems to imply the underlying states being extended, the signature of localization on transport quantities, such as the residual thermal conductivity, can still appear. For illustration, we consider a quasi-2d single band superconductor with no \(k_z\) dependence, and assume an isotropic Fermi surface as well as a \(|k|\) independent non-s wave order parameter, \(\Delta(\phi_k)\), where \(\phi_k\) is the azimuthal angle of \(k\). The residual thermal conductivity can be calculated from Eq. (6). After an integration along the direction perpendicular to the circular Fermi surface we get\(^{20,30,33,61}\)

\[
\frac{\kappa_0(\Gamma_N)}{T} \propto \left\langle \frac{1}{\Gamma_0(\omega = 0, \phi_k)} \left\{ 1 + C(\omega = 0, \phi_k) \right\} \right\rangle_{\phi_k}.
\]

(B1)

Here \(\Gamma_0(\omega, \phi_k) = \sqrt{(\text{Im}\Sigma_0)^2 + |\Delta(\phi_k)|^2}\) is the effective (frequency-dependent) impurity scattering rate of the superconducting state. If \(\Delta(\phi_k) \equiv 0\) it reduces to the normal state impurity scattering rate, \(\Gamma_N\). \(\text{Im}\Sigma_0\) is the imaginary part of the diagonal impurity self-energy in the Nambu particle-hole space at \(\omega = 0\), and it depends on \(\Gamma_N\). In Eq. (B1),

\[
1 + C(\omega = 0, \phi_k) = \frac{2 (\text{Im}\Sigma_0)^2}{(\text{Im}\Sigma_0)^2 + |\Delta(\phi_k)|^2}.
\]

(B2)

\(C(\omega, \phi_k)\) has been called a coherence factor in the literature, such as in Refs. 65 and 66, which, however, should not be confused with the usual coherence factors constructed from eigenfunctions of a BdG Hamiltonian. In Eq. (B1), it is precisely the \(1 + C\) factor that gives the large difference between the \(d\)-wave and isotropic chiral \(p\)-wave results in Fig. 1 at small \(\Gamma_N\). In the former case, \(\kappa_0(\Gamma_N)/\kappa_0(\Gamma_c)\) saturates to a nonzero constant as \(\Gamma_N \to 0\), while in the latter, it becomes vanishingly small. In the \(d\)-wave case, the \(\phi_k\) average in Eq. (B1) mainly comes from the \(\phi_k\) regime near the nodes where \(|\Delta(\phi_k)| \lesssim \text{Im}\Sigma_0\). As a consequence, \(1 \lesssim 1 + C \lesssim 2\) and it does not play a significant role. On the other hand, for the isotropic chiral \(p\)-wave, \(|\Delta(\phi_k)| \approx \Delta = \text{const}\). and \(1 + C \approx 2 (\text{Im}\Sigma_0)^2/|\Delta|^2 \to 0\) as \(\Gamma_N/\Gamma_c \to 0\). This additional dependence on \(\text{Im}\Sigma_0\) makes the \(\kappa_0/T\) vanish as \(\Gamma_N \to 0\) for the isotropic chiral \(p\)-wave, unlike the \(d\)-wave, even though the impurity induced density of states,
\[ N(\omega = 0), \text{ rises rapidly with } \Gamma_N \text{ in both cases},^{39,30,43} \]

i.e., \( N(0) \propto \text{Im} \Sigma_0 \propto \sqrt{\Gamma_N \Delta} \text{ at small } \Gamma_N, \text{ where } \Delta \text{ is the clean system gap magnitude (we have ignored a logarithmic correction to } N(0) \text{ for the d-wave).}

If the pairing is an anisotropic chiral p-wave with deep minima, \( \Delta_{\text{min}} \), then the behavior of \( \kappa_0/T \) can be similar to either the d-wave or the isotropic chiral p-wave case, depending on whether \( \text{Im} \Sigma_0 \lesssim \Delta_{\text{min}} \) or not in Eq. (B2). If we use \( \text{Im} \Sigma_0 \propto \sqrt{\Gamma_N \Delta} \), then the d-wave and isotropic chiral p-wave like regimes are delineated by \( \Gamma_N \sim \Delta_{\text{min}}^2/\Delta \). In other words, when \( \Gamma_N \gtrsim \Delta_{\text{min}} > \Delta_{\text{min}}^2/\Delta \) (as a conservative condition), we expect a \( \kappa_0/T \) behavior similar to that of the d-wave. Although the results here are obtained for a single band superconductor, similar conclusions hold for the multi-band pairing models that we considered in Fig. [1]

Since the residual thermal conductivity \( \kappa_0/T \) comes from the non-interacting Bogoliubov quasiparticle states at zero energy, we can write \( \kappa_0/T \) as

\[ \kappa_0/T \propto (C_v/T) v^2 \tau, \quad (B3) \]

where \( C_v/T \propto N(0) \) is the specific heat coefficient, \( v^2 \) is the mean square velocity of the Bogoliubov quasiparticles, and \( \tau \) is their effective mean free path. In the isotropic chiral p-wave case, from Eq. (B1), \( \kappa_0/T \propto (\text{Im} \Sigma_0)^2 \propto \Gamma_N \) at small \( \Gamma_N \). Taking \( v = v_F^{29} \) and using \( N(0) \propto \sqrt{\Gamma_N \Delta} \) we reach the conclusion that \( \tau \propto \sqrt{\Gamma_N \Delta} \rightarrow 0 \) as \( \Gamma_N \rightarrow 0 \), which implies localized zero energy Bogoliubov states induced by disorder. This is consistent with the single impurity result that a potential scatterer can induce Andreev bound states well below the isotropic chiral p-wave gap (similar to the conclusion reached for an s-wave superconductor with a paramagnetic impurity).\(^{25}\) In Eq. (B1), the Andreev bound state nature of the zero energy states is reflected in the \( 1 + C \) factor, which is why it makes a big difference between the isotropic chiral p-wave and d-wave.

A similar interpretation can be made for the d-wave case and leads to \( \tau \propto 1/\sqrt{\Gamma_N \Delta} \rightarrow \infty \) as \( \Gamma_N \rightarrow 0 \), indicating delocalized zero energy states, which, again, agrees with the single impurity result,\(^{25}\) although the localization issue of this case is quite subtle.\(^{35}\)

Appendix C: Disorder effects on the low energy density of states of s- and non-s-wave superconductors with accidental nodes or near-nodes

The different effects of disorder on accidental nodes or near-nodes in s-waves or non-s-wave superconductors are easily seen in the SCTA. Here, we show this difference in self-consistent BdG calculation of the disorder averaged density of states (DOS) at low energy.

In an s-wave superconductor, non-magnetic impurity scattering neither induces states below the minimum gap nor changes the k-space averaged gap magnitude, \( \Delta(k) \), within the SCTA.\(^{35}\) However, the difference of the gap magnitude from \( \Delta(k) \) at each \( k \) is renormalized by the disorder,\(^{35}\) and it decreases as the disorder increases, implying that the gap minima increase with disorder. This is indeed seen in Fig. [8] where we plot the disorder averaged DOS at different impurity concentrations, computed from self-consistent BdG for a single band s-wave superconductor with the following pairing gap function:\(^{47}\)

\[ \Delta(k) = \Delta_0 \left[ 1 - \cos(k_x + k_y) \right] \left[ 1 - \cos(k_x - k_y) \right]. \quad (C1) \]

\(|\Delta(k)|\) has the same nodal structure as d-wave along the diagonal, but \( \Delta(k) \) does not change sign near the nodes. The nodes are accidental rather than symmetry enforced. From Fig. [8] we see that the roughly linear DOS at low energy in the clean system gives way to a gap which grows with increasing disorder. Similar results have been observed in the SCTA.\(^{37}\) However, our self-consistent BdG result in Fig. [8] shows that the above conclusion about gap anisotropy holds even beyond the SCTA at very high impurity concentrations, where the spatial variations of the local order parameter become important.\(^{20,21,72}\) and the SCTA is not applicable.

In sharp contrast, near-nodes in non-s-wave superconductor do not increase, regardless of whether the order parameter is single-component or multi-component. This can be seen in Fig. [9] where the disorder averaged DOS is calculated for the two-component chiral p-wave model with deep gap minima, defined in Sec. [IV]. We see that the addition of a small amount of unitary scattering results in a filling in of the DOS at zero energy, similar to the single-component d-wave case.\(^{37}\) Similar results for a single band chiral p-wave superconductor with near-nodes have been obtained in Ref. [19] within the SCTA. As explained in the introduction, the quite different disorder effects on near-nodes in non-s-wave superconductors come from the fact that the anomalous impurity self energy vanishes.

Appendix D: Thermal Conductivity in BdG

The thermal conductivity tensor can be computed by the Kubo formula\(^{20,29}\) as

\[ \kappa_{\mu\nu} = \frac{1}{T} \lim_{\Omega \to 0} \frac{1}{\Omega} \lim_{q \to 0} \text{Im} \Lambda_{\mu\nu}(q, i\omega_m \to \Omega + i\delta). \quad (D1) \]

Here \( \Lambda_{\mu\nu}(q, i\omega_m) \) is the thermal current-current correlation function at Matsubara frequency \( \omega_m = 2\pi m/\beta \) with \( m \in \mathbb{Z} \) and \( \beta = 1/(k_B T) \). It is given by

\[ \Lambda_{\mu\nu}(q, i\omega_m) = \int_0^\beta d\tau e^{i\omega_m \tau} \left\langle T_{\tau} \left[ J_{\mu}(q, \tau) J_{\nu}(-q, 0) \right] \right\rangle, \quad (D2) \]

where \( \langle \cdots \rangle \) denotes thermal ensemble average for a given impurity configuration. \( J_{\mu}(q, \tau) \) is the imaginary-time thermal current operator along the \( \mu \) direction and can be approximately split into two parts

\[ J_{\mu}(q, \tau) \approx J_{\mu}^a(q, \tau) + J_{\mu}^b(q, \tau), \quad (D3) \]
where the superscripts $a$ and $b$ stand for the $d_{xz}$ and $d_{yz}$ orbital contributions, respectively. In this approximation the current due to the hybridization between $d_{xz}$ and $d_{yz}$ orbitals (from the hopping parameters $t_{ij}^{ab}$ and $t_{ij}^{\pm}$ in Eq. (15) of the main text) has been neglected. This is a good approximation given that the hybridization is one order of magnitude smaller than the nearest neighbor hopping. For the same reason we can approximate $\Lambda_{\mu\nu}(q, i\omega_n)$ by

$$\Lambda_{\mu\nu}(q, i\omega_n) \approx \Lambda_{\mu\nu}^{aa}(q, i\omega_n) + \Lambda_{\mu\nu}^{bb}(q, i\omega_n)$$

and ignore the cross correlation between current operators of different orbitals.

For the tight-binding model of Eq. (15), the thermal current operator of the orbital $a$ is given by

$$J_{\mu}^a(q = 0, \tau) \approx \frac{1}{N_x N_y} \sum_{ij, \sigma} \left( \mathbf{r}_i - \mathbf{r}_j \right)_\mu t_{ij}^{aa}$$

$$\times \frac{1}{2} \left[ \partial c_{i\alpha\sigma}(\tau) - c_{i\alpha\sigma}(\tau) \frac{\partial c_{j\alpha\sigma}(\tau)}{\partial \tau} \right].$$

where $c_{i\alpha\sigma}(\tau) = e^{\tau H} c_{i\alpha\sigma}^\dagger e^{-\tau H}$ and $c_{i\alpha\sigma}(\tau) = e^{\tau H} c_{i\alpha\sigma} e^{-\tau H}$ with $H$ the mean field BdG Hamilton. The prime in the summation means only sites $i$ and $j$ that are connected by nonzero hoppings $t_{ij}^{aa}$ are summed over. In this formula, $(\mathbf{r}_i - \mathbf{r}_j)_\mu t_{ij}^{aa}$ is the electron hopping velocity operator along the $\mu$-direction, where $\mathbf{r}_i$ is the coordinate of site $i$ on the square lattice. Also, Eq. (D5) only includes the kinetic energy part contribution to the thermal current, as indicated by the $\approx$ sign, and neglects the potential energy part or the superconducting order parameter part which is appropriate for Sr$_2$RuO$_4$, since its superconducting transition temperature $T_c$ is much smaller than the band hoppings.

Substituting Eq. (D5) into the definition of $\Lambda_{\mu\nu}^{aa}$ leads to

$$\Lambda_{\mu\nu}^{aa}(q = 0, i\omega_n) = \frac{1}{4(N_x N_y)^2} \sum_{ij, \sigma} \sum_{i'j', \sigma'} \left[ (\mathbf{r}_i - \mathbf{r}_j)_\mu t_{ij}^{aa} \right] \left[ (\mathbf{r}_{i'} - \mathbf{r}_{j'})_\nu t_{i'j'}^{aa} \right]$$

$$\times \int_0^\beta d\tau e^{i\omega_n\tau} \left\langle T_\tau \left\{ c_{i\alpha\sigma}^\dagger c_{j\alpha\sigma} c_{i'\alpha'\sigma'} c_{j'\alpha'\sigma'} - c_{i\alpha\sigma} c_{j\alpha\sigma} c_{i'\alpha'\sigma'}^\dagger c_{j'\alpha'\sigma'}^\dagger - c_{i\alpha'\sigma'}^\dagger c_{j\alpha'\sigma'} c_{i'\alpha\sigma}^\dagger c_{j'\alpha\sigma} + c_{i\alpha\sigma}^\dagger c_{j\alpha\sigma} c_{i'\alpha'\sigma'}^\dagger c_{j'\alpha'\sigma} \right\} \right\rangle, \quad (D6)$$
where

\[ \dot{c}_{i\alpha} = \frac{\partial c_{i\alpha \sigma}}{\partial \tau} = [H, c_{i\alpha \sigma}] = \sum_n E_n \left[ v^*_n(i) \gamma^\dagger_n \sigma - u_n(i) \gamma_n \sigma \right]. \]  \hspace{1cm} (D7)

In Eq. (D6) we have suppressed the \( \tau \) dependence of each operator product for brevity. Eq. (D7) is obtained by using the Bogoliubov transformation from Eq. (18) and the diagonalized BdG Hamiltonian \( H = \sum_{n, \sigma} E_n \gamma_{n \sigma} \gamma^\dagger_{n \sigma} \).

Next we plug Eq. (18) and (D7) into Eq. (D6), carry out the expectation value of each term in Eq. (D6) using Wick’s theorem, complete the imaginary time integral, and then perform the analytic continuation \( i\omega_n \rightarrow \Omega + i\delta \). The final result of \( \Lambda_{M\lambda}(q = 0, \Omega + i\delta) \) is fully in terms of the eigenvalues, \( E_n \), and eigen-functions, \( (u_{n\alpha \sigma}, v_{n\alpha \sigma}) \), of the BdG Hamiltonian \( H \) so that it can be evaluated numerically. Although the derivation is quite straightforward, the final expression is quite lengthy so we do not present it here.

27. The mixing between the two quasi-1d bands actually arises from a combination of inter-orbital hopping \( t'' \) and spin-orbit coupling (SOC), \( \lambda_{\text{SOC}} \). The \( \lambda_{\text{SOC}} \) extracted from LDA band splitting at the 2d Brillouin zone center is not small compared with the hopping parameter \( t \) however, its effect on the FS is perturbatively small near the (1, 1) direction, which suggests a smaller \( \lambda_{\text{SOC}} \) to be used in a tight-binding calculation to model the physics near the FS, as in Ref. 24.
For the 2-band model in Sec. III A the Bogoliubov quasi-particle energies were given in Ref. 75 in terms of orbital pairing gap functions, and can be transformed to the band particle energy in weak coupling, $\alpha, \beta, \gamma$. Along the $\beta$-band FS, where the lowest lying quasi-particle energy is realized, one finds in weak coupling, $E(k)^2 = |\Delta_\beta^{\text{intra}}(k)|^2 + O(\Delta_\beta^{\text{intra}}(k))$, where $\Delta_\beta^{\text{intra}}(k)$ is the $\beta$ intra-band pairing gap function, and $E_{\alpha,N}(k)$ is the $\alpha$-band normal state energy dispersion. Note, along the $\beta$-band FS, $E_{\alpha,N}(k) \neq 0$ and is on the order of the hopping parameters $t$, $t'$, or $t''$, which are $\gg |\Delta|$.

In Ref. 22 the $\text{RG}$ gap has been approximated by the same $\Delta_\beta(k)$ but with the three coefficients $(b_1, b_2, b_3) = (-0.4375, 1, 0)$, which, however, does not capture the smaller $\text{RG}$ gap function slope near the minima and, consequently, gives a residual thermal conductivity smaller than the one calculated in Fig. 1 black $\Delta$.

From the inverse participation ratio we find that the low energy states at the band bottom of Fig. 8 are localized when the impurity density is sufficiently large, suggesting a transition from the superconducting to a gapped insulating phase at large disorder, which is related to the breakup of the system into superconducting islands separated by non-superconducting sea. The results are qualitatively similar to those obtained in previous studies of isotropic $s$-wave superconductors with random chemical potential disorder.

More precisely, the velocity here should be the group velocity of Bogoliubov quasiparticles. However, this does not affect our qualitative discussions.

From the inverse participation ratio we find that the low energy states at the band bottom of Fig. 8 are localized when the impurity density is sufficiently large, suggesting a transition from the superconducting to a gapped insulating phase at large disorder, which is related to the breakup of the system into superconducting islands separated by non-superconducting sea. The results are qualitatively similar to those obtained in previous studies of isotropic $s$-wave superconductors with random chemical potential disorder.
