(Dated: September 30, 2021)

We extend an effective field theory developed to describe rotational bands in even-even nuclei to the odd-mass case. This organizes Bohr & Mottelson’s treatment of a particle coupled to a rotor as a model-independent expansion in powers of the angular velocity of the overall system. We carry out this expansion up to fourth order in the angular velocity and present results for ^{99}Tc , ^{159}Dy , $^{167,169}\text{Er}$, $^{167,169}\text{Tm}$, ^{183}W , ^{235}U and ^{239}Pu . In each case, the accuracy and breakdown scale of the effective field theory can be understood based on the single-particle and vibrational energy scales in that nucleus.

I. INTRODUCTION

For many even-even nuclei, the rotor model provides a good description of the energies of their low-lying states and of the transitions between them [1]. In this model, the nucleus is pictured as an axially symmetric quantum-mechanical rotor, whose eigenenergies are proportional to $I(I+1)$, with I the spin of the nuclear state. This picture can be extended to neighboring odd-mass nuclei by coupling a fermion to the rotor. This “particle-rotor” approach can be quite successful in describing the low-lying spectra and transitions. However, it also works markedly better in some nuclei than in others. The classic text by Bohr and Mottelson provided an extensive summary of the successes and challenges of such a picture already fifty years ago [1].

In this paper we re-cast the particle-rotor model as a systematic Effective Field Theory (EFT), building on the successful and systematic description of even-even systems as rotors by Coello Pérez and Papenbrock [2, 3]. In that EFT the rotor degree of freedom is its angular velocity, $\vec{\nu}$, and the Lagrangian is organized in powers of this quantity. Here we develop an EFT that also includes the fermion’s position and spin as degrees of freedom. There is similar recent work on a particle-rotor EFT by Papenbrock and Weidenmüller [4]. EFTs are systematic expansions for observables as they are organized in powers of a small parameter. In our particle-rotor EFT the small parameter is the angular velocity of the overall system. The EFT will thus be suitable for nuclei in which the energy associated with the rotor degree of freedom, E_{rot} , is smaller than the energy required to excite the fermion to a new quantum state, E_{sp} , or the energy at which the rotor ceases to be rigid, E_{vib} . The EFT can then also be understood as an expansion in powers of $\epsilon_{\text{vib}} \equiv E_{\text{rot}}/E_{\text{vib}}$ and $\epsilon_{\text{sp}} \equiv E_{\text{rot}}/E_{\text{sp}}$.

At leading order (LO) in this expansion the rotor is rigid and the fermion attached to it is in a specific quantum state [5]. The corresponding Lagrangian is the sum of that of a classical, axially-symmetric, rotor, parametrized by two Euler angles, and that for a fermion whose interaction with the rotor is governed by a specific potential, V , in the corotating or intrinsic frame. This is the starting point of Bohr and Mottelson’s particle-rotor model too. It yields a LO Hamiltonian

$$H^{(0)} = H_{\text{rot}} + H_{\text{ferm}}, \quad (1)$$

where

$$H_{\text{rot}} = \frac{\vec{R}^2}{2\mathcal{I}_0}, \quad H_{\text{ferm}} = T + V(\vec{r}, \vec{s}), \quad (2)$$

with $\vec{R} = \mathcal{I}_0 \vec{\nu}$ the rotor angular momentum and \mathcal{I}_0 its moment of inertia, while \vec{r} is the single-particle coordinate, T the corresponding kinetic energy, and \vec{s} the spin of the fermion. The eigenstates of $\hat{H}^{(0)}$ are direct products of eigenstates of \hat{H}_{rot} and eigenstates of \hat{H}_{ferm} , i.e., the single-particle orbitals [5]. The spectrum of the odd-mass system is then a sequence of rotational bands, each built on a single-particle orbital. A particular band is labeled by the projection of the fermion’s total angular momentum, \vec{j} , on the axis of the rotor, i.e., the component of \vec{j}/\hbar in the 3-direction in the intrinsic frame, typically denoted K .

Since the rotor is axially symmetric, K continues to be a good quantum number even when corrections to the LO Lagrangian are considered, i.e., when the fermion’s degrees of freedom become coupled to $\vec{\nu}$. Indeed, since V is the potential energy of the fermion in a rotating frame, rotational invariance requires that it contains a term proportional to $\vec{\nu}$: the Coriolis force. In this work we allocate all such couplings between $\vec{\nu}$ and the fermionic degrees of freedom to an additional piece of H , H_{coup} :

$$H = H_{\text{rot}}(\vec{\nu}) + H_{\text{ferm}}(\vec{r}, \vec{s}) + H_{\text{coup}}(\vec{\nu}, \vec{r}, \vec{s}). \quad (3)$$

EFTs are also model independent. To achieve that we make no assumption about $V(\vec{r}, \vec{s})$ or about H_{coup} , other

† coelloperez1@llnl.gov

‡ phillid1@ohio.edu

than that both are axially symmetric and the latter can be expanded in powers of \vec{v} . This is in contrast to the recent Ref. [6], which also tackled the rotor-plus-fermion problem, but assumed that V was a deformed harmonic oscillator potential, thereby adopting a model in which the fermion’s single-particle states are Nilsson-model orbitals.

Corrections induced by “cranking” the general fermion potential $V(\vec{r}, \vec{s})$, i.e., effects resulting from the fermion’s interaction with a rotating core, then appear in H_{coup} . The corresponding terms involve undetermined coefficients that are not related to $V(\vec{r}, \vec{s})$ by rotational symmetry. The leading piece of H_{coup} has the form of the Coriolis force and can be derived by defining a covariant derivative of the fermionic field [4]. This would appear to fix the coefficient of this $O(v)$ part of H_{coup} —as happens in the textbook treatment in Ref. [1]. However, in an EFT all operators consistent with the symmetries are permitted, and the same operator can also be induced by effects at the high scale E_{sp} . Therefore the coupling in this NLO piece of the Hamiltonian, which we denote $H_{\text{coup}}^{(1)}$, is not fixed. The impact of $H_{\text{coup}}^{(1)}$ on the system’s energy levels can be computed in first-order perturbation theory. As is well-known, in first order the effect is non-zero only for $K = 1/2$ bands, and represents the first correction to the “adiabatic limit” in which the fermion orbits are aligned with the symmetry axis of the deformed core. The high-energy dynamics is then summarized in the resulting formula for the energy levels of the odd-mass rotor by a matrix element of a fermionic operator.

At next-to-next-to-leading order ($N^2\text{LO}$), both H_{rot} and H_{coup} receive further corrections of order $O(v^2)$. Corrections to the former are due to the nonrigidity of the rotor. This also affects H_{coup} , as interaction with the spinning core can produce excitation to single-particle states with energies of order E_{sp} . Such effects must be parametrized by an effective operator of order $O(v^2)$ or higher (see Sec. II). These pieces of $H_{\text{coup}}^{(2)}$ renormalize the energy shift obtained from two insertions of $H_{\text{coup}}^{(1)}$, i.e., it gives the high-energy part of the second-order corrections to the adiabatic limit. While the even-even system is a straightforward expansion in ϵ_{vib} the odd-mass system’s energy levels show an interplay of expansions in ϵ_{vib} and in ϵ_{sp} .

In this paper we carry out this joint expansion up to fourth order in the expansion parameter, thus computing the energy levels of a rotational band in the odd-even system up to accuracy $(E_{\text{rot}}/E_{\text{high}})^3$, with E_{high} of order either E_{sp} or E_{vib} . The Hamiltonian’s expansion yields an expansion for energy levels in powers of the total angular momentum quantum number I . At each order in the expansion, new parameters appear and must be fit to data.

A common criticism of such a calculation is that it lacks predictive power. But our EFT for rotational bands is systematic: at n th order it yields a correction to the energy of the states in a nuclear rotational band that

scales in a definite way with the expansion parameter and with I :

$$(\Delta E)_{N^n\text{LO}} \sim E_{\text{rot}} \epsilon_{\text{sp}}^{n-1} I^n. \quad (4)$$

The error in the resulting n th-order EFT energy-level formula then scales as I^{n+1} . By analyzing the residuals of the EFT’s prediction at each order with respect to data we will show that such systematic improvement is indeed present in our description [7]. Moreover, we will show that the residuals encode information on the breakdown scale of the EFT. In general the convergence of the EFT is at least as good as is expected according to Eq. (4) and an *a priori* estimate of the energy scales E_{rot} , E_{sp} , and E_{vib} in the even-even and odd-mass nuclei under consideration.

The EFT is intrinsically limited to energy levels that lie below the energy scales E_{vib} and E_{sp} . In most nuclei these scales are below the energy at which pairing effects become dynamical. Pairing correlations are thus not explicitly treated in the EFT: effects associated with them are subsumed into the low-energy constants that multiply the terms of different degree in I in the EFT’s energy-level formula. We are *not* attempting to predict the moment of inertia of the nucleus, and so are agnostic about the microscopic effect that pairing (see, e.g., Refs. [8, 9]) has on it and other coefficients in our energy formula. That formula is essentially a polynomial in I for a particular rotational band; our rotor + fermion EFT has nothing to say about phenomena such as backbending and upbending. Backbending, upbending, and many other interesting phenomena can be addressed in DFT-based (e.g., [10–13]), shell-model (e.g., Refs. [13–16]), and *ab initio* (e.g., Refs. [17–21]) models of rotating nuclei. But these occur at high enough energies that the EFT is no longer a valid description of the rotational band there. We explicitly sacrifice the ability to describe these effects in order to obtain a description of the low-energy $E < E_{\text{vib}}, E_{\text{sp}}$ part of the band that is model independent and systematically improvable.

One example of the EFT’s model independence is that in the traditional rotor-model literature the Coriolis force that represents the $n = 1$ correction in Eq. (4) results in a “decoupling parameter” appearing in the formula for the energies of states in the band. In the particle-rotor EFT the decoupling parameter is not computed from single-particle matrix elements (cf. Ref. [6]). Our goal is not a microscopic description of the rotor-fermion system. Instead we seek a description that captures the long-distance features of this system, and parametrizes its short-distance details in terms of coefficients that are fit to data. EFT helps us obtain this organized phenomenology because it is agnostic about the short-distance details and organizes the energies of levels in the band in terms of an expansion in a small parameter.

We do *not* expand observables in powers of the fermion angular momentum \vec{j} or its projection on the rotor axis, K . This means that in our approach there is not just a single low-energy constant in $H_{\text{coup}}^{(1)}$, instead there is a

string of fermion operators that can multiply the Coriolis operator structure, each having its own coefficient. This interpretation of the “Coriolis operator” differs from that of Ref. [4], although the interpretational difference has no practical consequences for the energy-level formula. The lack of power counting for operators built solely from the fermion’s degrees of freedom means that although in principle it should be possible to connect our EFT to shell-model [14–16] or *ab initio* calculations [17–21] of rotational bands, this task will be complicated in practice because the parameters in the formula for the band energies actually represent matrix elements of arbitrary functions of j_3 , \vec{j} , and \vec{r} , as explained further in Sec. IV below.

The rest of the paper is structured as follows. In Sec. II we make some general remarks about the “integrating out” process that leads to the EFT of rotational bands developed here. This justifies the statements regarding operator suppression above. In Sec. III we specify the degrees of freedom, write down the leading-order Lagrangian, $L_{\text{rot}} + L_{\text{ferm}}$ and obtain the constants of the motion. Section IV discusses the allowed operators that can appear in L_{rot} and L_{coup} and the quantities by which each operator is suppressed, i.e., it develops the power counting for our EFT. Section V then uses the resulting expansion to derive the rotational band formula order-by-order in I , see Eq. (4). Section VI studies the extent to which the EFT describes rotational bands in $^{167,169}\text{Er}$, $^{167,169}\text{Tm}$, ^{239}Pu , ^{235}U , ^{159}Dy , ^{99}Tc , and ^{183}W . In each case we show that the accuracy of the band formula, and the number of levels for which it gives a systematic treatment of the spectrum, can be tied to the scales E_{rot} , E_{sp} , and E_{vib} for that particular nucleus. Finally, Sec. VII offers a summary and avenues for future work.

II. FROM A NUCLEONS TO AN EFT OF FERMION ROTATIONAL BANDS

Ab initio calculations that solve the quantum-mechanical many-body problem for a given nuclear Hamiltonian are now feasible for nuclei up to ^{100}Sn and beyond [22, 23]. Recent no-core configuration interaction calculations of the Be isotope chain have shown the emergence of rotational and shell-model degrees of freedom in these systems [17, 18, 20]. In this section we elucidate the relationship between a calculation with $A + 1$ nucleonic degrees of freedom and the rotor-plus-fermion EFT developed in this paper.

To get from one to the other we first imagine that we can solve the A -body problem and determine the spectrum of the corresponding Hamiltonian H_A . The solutions of

$$H_A|\phi_{R;n}\rangle = E_{R;n}|\phi_{R;n}\rangle \quad (5)$$

form a complete set of states for the A particles that make up the rotor. We label them by their total angular momentum and by another index n that allows us to

enumerate states of the same R . We divide those states into two groups: ones in the lowest-lying rotational band and states involving excitations that are predominantly of vibrational or single-particle character. The rotational band then forms a space \mathcal{P} , that will be included in our EFT, while the higher-energy states form a complementary space \mathcal{Q} . The gap between \mathcal{P} and \mathcal{Q} is assumed to be of order E_{vib} .

We now want to consider the interaction of the $A + 1$ th nucleon with the other A nucleons. This can be done by computing the optical potential if the nucleon has positive energy [24] or via a state-dependent effective potential. We take:

$$-\frac{\hbar^2 \nabla^2}{2m} \delta_{R'R} + V_{\text{eff};R'R}(\vec{r}, \vec{s}) = \langle \phi_{R';1} | H_{\text{eff};A+1}(E) | \phi_{R;1} \rangle, \quad (6)$$

to define the effective single-particle Hamiltonian in the situation where the rotor transitions from a state with total angular momentum R to one with angular momentum R' in the \mathcal{P} part of the space. The $H_{\text{eff};A+1}(E)$ whose matrix element appears on the right-hand side is the effective Hamiltonian that results from integrating out the effects of rotor states in the \mathcal{Q} space. It is equal to H_{A+1} plus corrections suppressed by powers of E/E_{vib} .

The hypothesis of the rotor-fermion picture is that in the intrinsic frame of the rotor the effective potential is the same for all states in the subspace \mathcal{P} , since those states are related to one another by rotations. Under this hypothesis the Hamiltonian defined by Eq. (6) can be taken to be $H_{\text{sp}}(\vec{r}, \vec{s})$: it depends only on the last nucleon’s spin and position. However this is only true to the extent that the rotor is rigid, i.e., all the states in the space \mathcal{P} are generated by rotations of the ground state of the rotor. Corrections to the picture then appears as a series in ϵ_{vib} .

In the intrinsic frame H_{sp} generates a set of single-particle states

$$H_{\text{sp}}|\psi_K\rangle = E_K|\psi_K\rangle \quad (7)$$

that are labeled by their spin projection on the intrinsic 3-axis, K . Since in that frame the rotor is not moving this spectrum has a ground state that is separated from all other states in the spectrum by an energy $\sim E_{\text{sp}}$.

We now focus on just that lowest state, sometimes called “the bandhead”. The particle-rotor EFT is based on the picture that the low-energy eigenstates of the $A + 1$ -body problem are, at LO in the EFT expansion, product states

$$|\psi_K\rangle|\phi_A\rangle, \quad (8)$$

where $|\phi_A\rangle \in \mathcal{P}$. These states form a rotational band, all built on the band-head K , where the fermion is to be thought of as in a particular single-particle state, while the core occupies one—or a superposition of several—of the rotational states that make up its ground-state band.

The EFT Hamiltonian for this rotational band is obtained from the single-particle Hamiltonian by integrating out all the single-particle states other than K . It

therefore differs from H_{sp} by operators that are suppressed by E/E_{sp} . In the rest of this section we determine the operators that can appear in this EFT Hamiltonian.

A. Allowed operators

In Ref. [3] the Lagrangian, and hence the Hamiltonian, could not depend on \hat{e}_3 , the rotor axis (the 3-axis in the body-fixed/intrinsic frame), because of spontaneous symmetry breaking. However, here the rotor is interacting with the fermion and dependence on \hat{e}_3 is permitted in H_{coup} . The rotor operators that can appear in H_{coup} in the EFT then have the parity and time-reversal properties listed in Table I. Meanwhile we take the fermionic operators appearing in H_{coup} to be its co-ordinate \vec{r} and its total angular momentum \vec{j} . Since \vec{r} can be transformed to $\{r, \vec{l}\}$ with \vec{l} the angular momentum vector, and $\vec{j} = \vec{l} + \vec{s}$ the two vectors \vec{r} and \vec{s} are sufficient to completely describe the fermion's state. Their discrete-symmetry properties are then shown in Table I.

Operator	P	T	Operator	P	T
\vec{v}	+	-	\vec{j}	+	-
\hat{e}_3	-	+	\vec{r}	-	+

TABLE I. Operators describing the state of the rotor (left block) and fermion (right block), together with their properties under parity and time reversal. Note that \vec{v} is an angular velocity, which explains the otherwise peculiar looking parity assignment.

We can also build even-rank tensors of the parity-mixed dot products, e.g.

$$\left(\hat{e}_3 \cdot \vec{j}\right)^2, \quad (\vec{v} \cdot \vec{r})^2 - \frac{1}{3} \vec{v}^2 \vec{r}^2, \quad \vec{v}^2 \vec{r}^2. \quad (9)$$

The first operator in this list can be absorbed into L_{ferm} since $\hat{e}_3 \cdot \vec{j} = K$, the projection of the fermion spin on the rotor axis. The other operators listed cannot be eliminated in this way, and will appear in $L_{\text{coup}}^{(2)}$, the Lagrangian that produces the piece of H_{coup} that is second order in \vec{v} .

Note that \hat{e}_3 can change the R quantum number of the rotor. Symmetry under reflection in the rotor's central plane (\mathcal{R} symmetry [1]) guarantees that only even powers of $\hat{e}_3 \cdot \vec{r}$ can appear. Such operators then only change the rotor R by 2, i.e., move from one rotor state (0^+ , 2^+ , etc.) to another.

B. Suppression by powers of \vec{v} —and nothing else

Permitted operators that couple rotor and fermionic degrees of freedom, and are not already accounted for in

the fermionic potential are then, up to second order in v :

$$\begin{aligned} O_1 &= \vec{v} \cdot \vec{j}; \\ O_{2a} &= \vec{v}^2 \vec{j}^2; \\ O_{2b} &= (\vec{v} \cdot \vec{j})^2 - \frac{1}{3} \vec{v}^2 \vec{j}^2; \\ O_{2c} &= \vec{v}^2 \vec{r}^2; \\ O_{2d} &= (\vec{v} \cdot \vec{r})^2 - \frac{1}{3} \vec{v}^2 \vec{r}^2. \end{aligned} \quad (10)$$

However, there is no reason for the expectation value of \vec{j}^2 in the fermionic state to be small. Indeed, we expect it to be a number of order one. Furthermore, the operator \vec{r}^2 should generate an expectation value of order $\hbar^2/(\sqrt{2\mu E_{\text{sp}}})^2$ since, by the uncertainty principle, the fermionic wave function should have this spatial extent. This means, then, that powers of \vec{j}^2 and \vec{r}^2 are not suppressed. The only expansion we have, then, is the one in powers of the rotor velocity \vec{v} . This fact is not apparent in the Lagrangians developed in Ref. [4].

In fact, each operator in the list above can be multiplied by an arbitrary function of the scalar (and P- and T-even) quantities \vec{j}^2 , $(\vec{j} \cdot \hat{e}_3)^2$, \vec{r}^2 , $(\vec{r} \cdot \hat{e}_3)^2$, and $(\vec{j} \cdot \vec{r})^2$. As long as we are concerned only with the fermionic matrix element for a specific single-particle state $|\psi_K\rangle$ this doesn't matter: it just means that the coefficient of the operator with a particular power of v and a particular tensor structure is a matrix element of an arbitrary function of fermionic operators with the appropriate symmetry properties. But, since we don't know the fermionic wave function anyway, this additional ignorance regarding the fermionic operator has no practical consequence. Unlike Bohr and Mottelson or Ref. [6] we do not try to compute the matrix elements of the fermionic operators in Eq. (10) by assuming a particular description of single-particle states. Instead we fit them to data.

III. DEGREES OF FREEDOM AND LEADING-ORDER LAGRANGIAN

A. Parametrizing the rotor

In this section we review the parametrization of the rotor introduced in Ref. [2] and used in Ref. [3]. We start with the transformation properties of the elements $g \equiv g(\alpha, \beta)$ under $\text{SO}(3)/\text{SO}(2)$ rotations, as they parametrize the orientation of the rotor. Indeed, the rotation

$$g^{-1} = e^{i\beta J_2} e^{i\alpha J_3}, \quad (11)$$

where \vec{J} is the generator of rotations, aligns the laboratory or extrinsic reference frame with the co-rotating or intrinsic reference frame. In the latter, the 3-axis coincides with the symmetry axis of the rotor. The dynamics of the rotor are thus determined by the time derivative of g . For simplicity we study how $g^{-1} \partial_t g$ transforms under

rotations. Being an element of the Lie algebra of $SO(3)$, it can be written as

$$g^{-1}\partial_t g = iv_1 J_1 + iv_2 J_2 + iv_3 J_3. \quad (12)$$

Employing the BakerCampbellHausdorff formula we write the components of \vec{v} in terms of the rotor's orientation angles and their time derivatives

$$v_1 = \dot{\alpha} \sin \beta, \quad v_2 = -\dot{\beta}, \quad v_3 = -\dot{\alpha} \cos \beta. \quad (13)$$

Under the rotation $r \equiv r(\varphi, \theta, \gamma)$, the element $g^{-1}\partial_t g$ transforms into [2]

$$g^{-1}\partial_t g \rightarrow \tilde{g}^{-1}\partial_t \tilde{g} = i\tilde{v}_1 J_1 + i\tilde{v}_2 J_2 + i\tilde{v}_3 J_3. \quad (14)$$

where $\tilde{g} \equiv g(\tilde{\alpha}, \tilde{\beta})$ and the angles $\tilde{\alpha}$, $\tilde{\beta}$ and $\tilde{\gamma}$ are complicated functions of both the orientation angles and those defining the rotation r . The components of the transformed element \vec{v} are

$$\begin{pmatrix} \tilde{v}_1 \\ \tilde{v}_2 \end{pmatrix} = \begin{pmatrix} \cos \tilde{\gamma} & -\sin \tilde{\gamma} \\ \sin \tilde{\gamma} & \cos \tilde{\gamma} \end{pmatrix} \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}, \quad \tilde{v}_3 = v_3 + \dot{\tilde{\gamma}}. \quad (15)$$

These equations show that under an $SO(3)$ rotation v_1 and v_2 transform as the x and y components of a vector would under the rotation $\tilde{h} \equiv h(\tilde{\gamma}) = e^{-i\tilde{\gamma}J_3}$, allowing us to easily write rotationally-invariant objects from these components.

B. Fermion representation

The transformation properties of the fermion field were discerned in Ref. [2]. Let Φ represent the fermion field in the intrinsic reference frame. Then, the fermion field in the extrinsic frame, Ψ , can be written as

$$\Psi = g\Phi. \quad (16)$$

From this expression, it can be shown that under rotations, the intrinsic fermion field transforms as

$$\Phi \rightarrow \tilde{\Phi} = \tilde{h}\Phi, \quad (17)$$

allowing us to write rotationally-invariant objects from the intrinsic fermion field with ease. Similarly, if the covariant derivative is defined as

$$D_t \equiv \partial_t + iv_3 J_3 = \partial_t - i\dot{\alpha} \cos \beta J_3, \quad (18)$$

the covariant derivative of the intrinsic field, $D_t \Phi$, transforms as

$$D_t \Phi \rightarrow \tilde{D}_t \tilde{\Phi} = \tilde{h} D_t \Phi. \quad (19)$$

We can parametrize Φ in terms of the angles γ and θ specifying the orientation of the fermion's total angular momentum in the intrinsic frame. For example, a fermion in a spin-half orbital would take the form

$$\Phi = \phi e^{-i\gamma J_3} e^{-i\theta J_2} \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad (20)$$

where ϕ is the solution to the part of the rotor's potential that does not change under rotations. This means that ϕ carries the radial dependence i.e., $\phi(r)$. We note that rotations around the symmetry axis are arbitrary for an axially-symmetric system. So we choose to write the fermion in a different form that will be useful in what follows. We write

$$\Phi = e^{-i\gamma J_3} \xi, \quad (21)$$

where ξ is the fermion state in the intrinsic frame with the choice $\gamma = 0$, i.e.

$$\xi = \phi e^{-i\theta J_2} \begin{pmatrix} 1 \\ 0 \end{pmatrix}. \quad (22)$$

We then rewrite the fermion in the extrinsic frame as

$$\Psi = r(\alpha, \beta, \gamma) \xi. \quad (23)$$

Even though we have shown the parametrization in equations (20) and (22) for a fermion in a spin-half orbital, equation (23) is general. We also note that even though the choice of γ is arbitrary $\dot{\gamma}$ isn't, since $\dot{\gamma}$ could couple to other degrees of freedom and we chose γ to be part of the rotational degrees of freedom.

Note that this intrinsic frame constitutes an additional choice beyond that made at the start of this section: we exploit the symmetry of the rotor around the 3-axis to choose an intrinsic frame in which the fermion spin vector lies in the 1-3 plane. In this frame the components of the element \vec{v} are obtained by studying the dynamics of the element $r^{-1}\partial_t r$:

$$\begin{aligned} v_1 &= \dot{\alpha} \sin \beta \cos \gamma - \dot{\beta} \sin \gamma, \\ v_2 &= -\dot{\alpha} \sin \beta \sin \gamma - \dot{\beta} \cos \gamma, \\ v_3 &= -\dot{\alpha} \cos \beta - \dot{\gamma}. \end{aligned}$$

C. Constructing the leading-order Lagrangian

We separate the Lagrangian into a term involving the rotational degrees of freedom of the whole system (i.e. \vec{v}), a term involving the fermionic degrees of freedom, \vec{r} and \vec{s} , and a term encoding the coupling between the fermion and the overall rotational motion

$$L = L_{\text{rot}} + L_{\text{ferm}} + L_{\text{coup}}. \quad (24)$$

Here

$$L_{\text{ferm}} = \frac{1}{2} m \left(\frac{d\vec{r}}{dt} \right)^2 - V(\vec{r}, \vec{s}) \quad (25)$$

where $V(\vec{r}, \vec{s})$ is the aforementioned single-particle effective potential. Meanwhile L_{rot} is as discussed in Ref. [3], and is built out of powers of \vec{v} —or more specifically $v_{+1}v_{-1}$.

A Lagrangian consisting of v_{+1} , v_{-1} , ξ , and $D_t \xi$ that is invariant under rotations of the subgroup $SO(2)$ will

be invariant under the full action of the group $SO(3)$. We write the LO Lagrangian in the intrinsic frame as

$$\begin{aligned} L_{\text{LO}} &= C_0 v_{+1} v_{-1} + \xi^\dagger i D_t \xi - \xi^\dagger H_{\text{int}} \xi \\ &= \frac{C_0}{2} (\dot{\alpha}^2 \sin^2 \beta + \dot{\beta}^2) \\ &\quad + q |\phi|^2 \dot{\alpha} \cos \beta \cos \theta \\ &\quad + q \dot{\gamma} |\phi|^2 \cos \theta + i \phi^* \dot{\phi} - \xi^\dagger H_{\text{int}} \xi, \end{aligned} \quad (26)$$

where q is the total angular momentum of the fermion in the intrinsic frame.

The physics content of this Lagrangian is clearer if we compute the matrix elements of the fermion's angular momentum. Defining $j_k \equiv \xi^\dagger J_k \xi$ for $k = 1, 2, 3$ we have

$$\begin{aligned} j_1 &= q |\phi|^2 \sin \theta, \\ j_2 &= 0, \\ j_3 &= q |\phi|^2 \cos \theta. \end{aligned} \quad (27)$$

We also note that $i \xi^\dagger \partial_t \xi = i \phi^* \dot{\phi}$. The conjugate momenta for the co-ordinates ϕ , α , β , and γ are then

$$\begin{aligned} p_\phi &= i \phi^*, \\ p_\alpha &= C_0 \dot{\alpha} \sin^2 \beta + \cos \beta j_3, \\ p_\beta &= C_0 \dot{\beta}, \\ p_\gamma &= q |\phi|^2 \cos \theta. \end{aligned} \quad (28)$$

We note that $p_\gamma = \xi^\dagger J_3 \xi$, so, as expected, the component of the total angular momentum along the rotor symmetry axis comes entirely from the fermion. The LO Hamiltonian associated with the Lagrangian (26) then takes the more transparent form

$$H_{\text{LO}} = \frac{1}{2C_0} \left[\left(\frac{p_\alpha - \cos \beta p_\gamma}{\sin \beta} \right)^2 + p_\beta^2 \right] + \xi^\dagger H_{\text{int}} \xi \quad (29)$$

This Hamiltonian can be cast in an even simpler form if we rewrite it in terms of the total angular momentum of the system, \vec{Q} . The expressions for the components of this constant of motion in the extrinsic frame are (see Appendix D of Ref. [2] for details)

$$\begin{aligned} Q_x &= -p_\alpha \cot \beta \cos \alpha - p_\beta \sin \alpha + p_\gamma \frac{\cos \alpha}{\sin \beta}, \\ Q_y &= -p_\alpha \cot \beta \sin \alpha + p_\beta \cos \alpha + p_\gamma \frac{\sin \alpha}{\sin \beta}, \\ Q_z &= p_\alpha. \end{aligned} \quad (30)$$

The expression for the intrinsic components Q_1 , Q_2 and Q_3 can be obtained from the ones above by means of the rotation r^{-1} . In terms of the square of the total angular momentum,

$$\vec{Q}^2 = p_\beta^2 + \frac{1}{\sin^2 \beta} (p_\alpha - \cos \beta p_\gamma)^2 + p_\gamma^2 \quad (31)$$

the LO Hamiltonian can be written as

$$H_{\text{LO}} = \frac{1}{2C_0} (\vec{Q}^2 - p_\gamma^2) + \xi^\dagger H_{\text{int}} \xi \quad (32)$$

IV. HIGHER-ORDER TERMS

As discussed in section II, the LO Lagrangian (26) can be systematically improved by including permitted operators coupling rotor and fermion degrees of freedom with increasing powers of the low-energy operator v . These operators effectively account for the interaction between the rotor and the fermion and the nonrigidity of the former.

The order-by-order construction of the effective Hamiltonian is achieved employing Fukuda's inversion method to expand the generalized velocities of the rotor, $\dot{x} \in \{\dot{\alpha}, \dot{\beta}\}$, in power series of the dual expansion parameters $\epsilon_{\text{vib}}, \epsilon_{\text{sp}}$:

$$\dot{x} = \sum_m \dot{x}^{(m)}, \quad (33)$$

where $\dot{x}^{(m)} \sim \dot{x}^{(0)} \epsilon^m$. We remind the reader that in this work we do not attempt an EFT expansion for the single-particle potential $V_{\text{sp}}(\vec{r}, \vec{s})$. Furthermore, since we have no power counting for fermionic operators any combination of them permitted by symmetries can multiply an operator of a given order in v .

Nevertheless, if we consider the leading-order Lagrangian for the rotor then, if we write the generalized velocities as expansions in powers of $(\epsilon_{\text{sp}}, \epsilon_{\text{vib}})$, it can be symbolically written as

$$\begin{aligned} L_{\text{LO}} &= C_0 (v^{(0)} + v^{(1)} + \dots)_{+1} (v^{(0)} + v^{(1)} + \dots)_{-1} \\ &= C_0 v_{+1}^{(0)} v_{-1}^{(0)} + C_0 v_{+1}^{(0)} v_{-1}^{(1)} + C_0 v_{-1}^{(1)} v_{+1}^{(0)} + \dots \end{aligned} \quad (34)$$

The second and third terms in the second line here are $(\epsilon_{\text{sp}}, \epsilon_{\text{vib}})$ times smaller than the first one, and must be accounted for when computing the $O(v)$ piece of the Hamiltonian. The terms in \dots are suppressed by additional powers of the small parameter and are included in corrections to H at $O(v^2)$ and beyond.

A. Leading rotor-fermion coupling

At lowest order in \vec{v} , the only relevant term correcting the LO Lagrangian is

$$\Delta L_{\text{NLO}} = C_1 (v_{+1} j_{-1} + v_{-1} j_{+1}). \quad (35)$$

The next-to-leading order (NLO) correction to the Hamiltonian can be written as

$$\Delta H_{\text{NLO}} = p_\alpha \dot{\alpha}^{(1)} + p_\beta \dot{\beta}^{(1)} - L_{\text{LO}}^{(1)} - \Delta L_{\text{NLO}}^{(1)}. \quad (36)$$

Notice that this correction includes a contribution from the LO part of the Lagrangian, as discussed above. Inserting the expressions for the components of the generalized velocities in the above equation yields

$$\Delta H_{\text{NLO}} = \frac{C_1}{C_0} (j_{+1} Q_{-1} + j_{-1} Q_{+1}), \quad (37)$$

where we have defined $j_{\pm 1} = \xi^\dagger(J_1 \pm iJ_2)\xi/\sqrt{2} = q|\phi|^2 \sin \theta/\sqrt{2}$ and $Q_{\pm 1} = (Q_1 \pm iQ_2)/\sqrt{2}$, and used the identity

$$j_{+1}Q_{-1} + j_{-1}Q_{+1} = q|\phi|^2 \sin \theta \times \left(p_\beta \sin \gamma - \frac{p_\alpha}{\sin \beta} \cos \gamma + \frac{\cos \beta}{\sin \beta} p_\gamma \cos \gamma \right). \quad (38)$$

The operator structure of this correction is identical to that of the Coriolis term obtained by writing a rotationally-invariant Lagrangian for the particle-rotor system in the extrinsic frame

$$L_{\text{ext}} = C_0 v_{+1} v_{-1} + \Psi^\dagger i \partial_t \Psi - \Psi^\dagger H_{\text{ext}}^{(f)} \Psi, \quad (39)$$

and rotating it to the intrinsic one by means of the rotation r

$$\begin{aligned} L_{\text{int}} &= C_0 v_{+1} v_{-1} + \xi^\dagger r^{-1} i \partial_t r \xi - \xi^\dagger r^{-1} H_{\text{ext}}^{(f)} r \xi \\ &= C_0 v_{+1} v_{-1} - \vec{v} \cdot \vec{j} + \xi^\dagger i \partial_t \xi - \xi^\dagger H_{\text{int}}^{(f)} \xi, \end{aligned} \quad (40)$$

This intrinsic Lagrangian yields a Hamiltonian

$$\begin{aligned} H_{\text{int}} &= \frac{1}{2C_0} (\vec{Q} - \vec{j})^2 + \xi^\dagger H_{\text{int}}^{(f)} \xi \\ &= \frac{1}{2C_0} [\vec{Q}^2 - 2(j_{+1}Q_{-1} + j_{-1}Q_{+1})] + \xi^\dagger \tilde{H}_{\text{int}}^{(f)} \xi, \end{aligned} \quad (41)$$

with $\tilde{H}_{\text{int}}^{(f)} \equiv H_{\text{int}}^{(f)} + \vec{j}^2 - 2j_3^2$. This is equivalent to the rotor-fermion model Hamiltonian of Bohr and Mottelson [1], and similar to our NLO effective Hamiltonian, $H_{\text{NLO}} = H_{\text{LO}} + \Delta H_{\text{NLO}}$. Notice, however, that the coefficient accompanying the ‘‘Coriolis’’ term stemming from Eq. (37) is undetermined. In contrast the Coriolis term in the Bohr and Mottelson Hamiltonian is determined by the requirement of rotational invariance in the extrinsic frame—this is, after all, a classical-mechanics argument to this point.

Papenbrock and Weidenmüller point out that the fact that C_1 is not determined by symmetries and so is $\neq -1$ can be understood as a consequence of the presence of a gauge coupling that modifies the interaction of the fermion with the rotor velocity field that is generated by minimal substitution [4]. In fact, the coefficient appearing in Eq. (37) should not be understood as a number: any fermionic operator— \vec{j}^2 , $(\vec{j} \cdot \hat{e}_3)^2$, \vec{r}^2 , $(\hat{e}_3 \cdot \vec{r})^2$ —can appear in it. Therefore the full correction to the Hamiltonian at NLO in our expansion in powers of ϵ_{sp} is:

$$\Delta H_{\text{NLO}} = f(\vec{j}^2, (\vec{j} \cdot \hat{e}_3)^2, \vec{r}^2, (\hat{e}_3 \cdot \vec{r})^2)(j_{+1}Q_{-1} + j_{-1}Q_{+1}), \quad (42)$$

where f encodes an arbitrary string of fermionic operators. We will see below that the distinction between f and C_1/C_0 is irrelevant as far as practical application of this EFT is concerned, since the matrix element of the quantum-mechanical operator $f(\dots)\vec{j}$ in the fermionic state on which the band is built determines the size of the NLO effect in that band.

B. Corrections to the rotor-fermion coupling

Operators involving more powers of v improve the rotor-fermion interaction in Eq. (35). The $O(v^2)$ correction to this ‘‘Coriolis’’ term is

$$\Delta L_{\text{N}^2\text{LO}} = \frac{C_2}{2} (v_{+1}j_{-1} + v_{-1}j_{+1})^2 + D_2 (v_{+1}v_{-1})\vec{j}^2. \quad (43)$$

Including this contribution to the effective Lagrangian and the second-order components of the generalized velocities in the effective Hamiltonian yields an N^2LO correction

$$\begin{aligned} \Delta H_{\text{N}^2\text{LO}} &= -\frac{C_2}{2C_0^2} (j_{+1}Q_{-1} + j_{-1}Q_{+1})^2 \\ &\quad - \frac{D_2}{2C_0^2} (\vec{Q}^2 - j_3^2)\vec{j}^2 \\ &\quad + \frac{C_1^2}{C_0} (j_1^2 + j_2^2). \end{aligned} \quad (44)$$

It is important to mention that our lack of knowledge of the details of the single-particle states makes it impossible to disentangle the matrix elements of the third term in this correction from those of H_{ferm} . The effects of this term are thus taken into account already at LO.

In a similar way, including the N^3LO contribution to the Lagrangian

$$\begin{aligned} \Delta L_{\text{N}^3\text{LO}} &= \frac{C_3}{3} (v_{+1}j_{-1} + v_{-1}j_{+1})^3 \\ &\quad + \frac{2D_3}{3} (v_{+1}v_{-1})(v_{+1}j_{-1} + v_{-1}j_{+1}) \end{aligned} \quad (45)$$

and the third-order components of the generalized velocities, yields the N^3LO correction to the Hamiltonian

$$\begin{aligned} \Delta H_{\text{N}^3\text{LO}} &= \frac{C_3}{3C_0^3} (j_{+1}Q_{-1} + j_{-1}Q_{+1})^3 \\ &\quad + \frac{D_3}{3C_0^3} (\vec{Q}^2 - j_3^2)(j_{+1}Q_{-1} + j_{-1}Q_{+1}) \\ &\quad - \frac{C_1}{C_0^2} [j_{+1}Q_{-1} + j_{-1}Q_{+1}][C_2(j_1^2 + j_2^2) + D_2\vec{j}^2]. \end{aligned} \quad (46)$$

Again, the matrix elements of the third term cannot be disentangled from those of ΔH_{NLO} , and thus those effects are taken into account at that order.

This pattern is generic: the relevant terms in the order n correction to the Hamiltonian always come from $-\Delta L_{\text{N}^n\text{LO}}(\dot{x}^{(0)})$. Terms in the n th-order piece of the Lagrangian, $\Delta L_{\text{N}^n\text{LO}}$, that contain $(v_{+1}v_{-1})^n$ and $(v_{+1}j_{-1} + v_{-1}j_{+1})^n$ therefore translate into corrections to the Hamiltonian containing $(\vec{Q}^2 - j_3^2)^n/2^n C_0^{2n}$ and $(j_{+1}Q_{-1} + j_{-1}Q_{+1})^n/C_0^n$, respectively.

It then follows that the fourth-order contribution to the Lagrangian,

$$\begin{aligned} \Delta L_{\text{N}^4\text{LO}} &= \frac{C_4}{4} (v_{+1}j_{-1} + v_{-1}j_{+1})^4 \\ &\quad + \frac{D_4}{2} (v_{+1}v_{-1})(v_{+1}j_{-1} + v_{-1}j_{+1})^2, \end{aligned} \quad (47)$$

yields the correction to the Hamiltonian

$$\begin{aligned} \Delta H_{N^4LO} = & \frac{C_4}{4C_0^4} (j_{+1}Q_{-1} + j_{-1}Q_{+1})^4 \\ & + \frac{D_4}{4C_0^4} (\vec{Q}^2 - j_3^2)(j_{+1}Q_{-1} + j_{-1}Q_{+1})^2 \quad (48) \\ & + \dots \end{aligned}$$

where the dots stand for terms whose matrix elements cannot be disentangled from those of lower-order corrections.

C. Corrections to the rotor Lagrangian

Besides effectively accounting for the interaction between the nucleons in the rotor and the fermion, higher-order contributions to the Lagrangian account for other effects. As shown in Ref. [3] adding a term of the form

$$\Delta L_{\text{rotor subleading}} = E_4 (v_{+1}v_{-1})^2 \quad (49)$$

to the effective Lagrangian improves the description of the ground-state rotational bands in even-even nuclei. Including this term in our Lagrangian yields the correction to the Hamiltonian

$$\Delta H_{\text{rotor subleading}} = \frac{E_4}{4C_0^4} (\vec{Q}^2 - j_3^2)^2. \quad (50)$$

This correction, however, is not suppressed in the same way as the operators discussed up until this point since it does not arise from integrating out fermionic states. In Ref. [3] the suppression of this correction was established to be $(E_{\text{rot}}/E_{\text{vib}})^2 = \epsilon_{\text{vib}}^2$. For most of the systems considered in this work $(E_{\text{rot}}/E_{\text{vib}})^2 \lesssim (E_{\text{rot}}/E_{\text{high}})^3$, and thus we can treat the correction (50) as part of the N^4LO correction to the Hamiltonian.

V. ENERGY FORMULA FOR ROTATIONAL BANDS

Now that we have an order-by-order expansion for the Hamiltonian of the rotor-fermion system in hand, we will use it to systematically compute the energies of states in rotational bands with definite K , seeking an expansion for those energies in powers of the same two expansion parameters used to organize the Hamiltonian in the previous section, i.e., ϵ_{sp} and ϵ_{rot} .

A. Leading order

Let us return to the expression for the LO Hamiltonian in Eq. (32). In what follows we take this classical function of the co-ordinates $\alpha, \beta, \gamma, \theta$ and ϕ , and treat it as a quantum-mechanical operator with \hat{Q} and \hat{J} acting

on the rotational and fermionic degrees of freedom, respectively. The eigenstates of the intrinsic single-particle Hamiltonian \hat{H}_{int} , simultaneously eigenstates of \hat{Q}_3 , are denoted by ξ_K

$$\hat{H}_{\text{int}}\xi_K = E_K\xi_K. \quad (51)$$

We note that since these states are eigenstates of \hat{Q}_3 they do not correspond to a definite θ , i.e., the representation (22) does not apply from this point on. For the rotational portion of the Hamiltonian we choose the Euler angle $(\alpha-\beta-\gamma)$ representation, for which the eigenstates of the rotor Hamiltonian $\hat{H}_{\text{rot}} = (\hat{Q}^2 - \hat{p}_\gamma^2)/2C_0$ are Wigner D-functions, denoted by $\mathcal{D}_{MK}^I \equiv \mathcal{D}_{MK}^I(\alpha, \beta, \gamma)$

$$\hat{H}_{\text{rot}}\mathcal{D}_{MK}^I = \frac{\hbar^2 I(I+1) - \hbar^2 K^2}{2C_0} \mathcal{D}_{MK}^I. \quad (52)$$

We focus on nuclei for which the band under study, defined by its value for K , is well separated from bands with $\hat{Q}_3 = \hbar(K \pm 1)$. For these systems states in the band of interest can be described in terms of only one single-particle state ξ_K : mixing between it and $\xi_{K \pm 1}$ is a perturbative effect. If the splitting between E_K and E_{K+1} (say) is “accidentally” smaller than the typical single-particle energy scale E_{sp} (instead it is of order E_{rot}) then both states must be considered as low-energy degrees of freedom in the rotational EFT. Significant inter-band mixing results. The consequences of this were discussed by Rowe for the case of ^{183}W (cf. also Sec. VIE below) [5] and by Papenbrock and Weidenmüller for ^{187}Os [4].

But, in nuclei for which $|E_{K \pm 1} - E_K| \gg E_{\text{rot}}$ product states

$$\left(\frac{2I+1}{8\pi^2}\right)^{1/2} \xi_K \mathcal{D}_{MK}^I \quad (53)$$

are eigenstates of \hat{H}_{LO} corresponding to eigenvalues

$$\begin{aligned} E_{\text{LO}}(I, K) = & \langle KIM | \hat{H}_{\text{LO}} | KIM \rangle \\ = & A_{\text{rot}} I(I+1) + \tilde{E}_K. \end{aligned} \quad (54)$$

Here A_{rot} is the constant $\hbar^2/2C_0$ and \tilde{E}_K is the energy of the fermion in the intrinsic frame, E_K , minus $\hbar^2 K^2/2C_0$. It is important to note that the Euler angles in the Wigner D-function describe the motion of the system as a whole, and not just that of the rotor to which the fermion is coupled. Correspondingly, I, M , and K are the eigenvalues of \hat{Q}^2, \hat{Q}_z , and \hat{Q}_3 , where \hat{Q} is the total angular-momentum operator of the rotor-plus-fermion system. This system is then described by a wave function that is the product of the wave function of the fermion in the intrinsic frame and the wave function of the rotational motion of the system as a whole [1].

Equation (54) is the leading term in an adiabatic expansion for the energy of states in the K rotational band. The adiabatic expansion is useful when (\hbar times) the rotational frequency of the system is small compared to

the excitation energies of the fermion in the rotor's potential. That states of the form (53) represent the wave function of the rotor-plus-fermion system at LO in such an expansion is emphasized by, e.g., Rowe in Ref. [5].

The \mathcal{R} symmetry of the system results in the state proportional to $\xi_{\bar{K}} \mathcal{D}_{M-K}^I$ having the same energy as the state (53). ($\xi_{\bar{K}}$ is obtained from ξ_K by applying the \mathcal{R} -parity operator, see Bohr and Mottelson, Eq. (4-17).) It follows that the LO wave function of the rotor-fermion system is the one written in Bohr and Mottelson Eq. (4A-5)

$$\Psi_{KIM} = \left(\frac{2I+1}{16\pi^2} \right)^{1/2} [\xi_K \mathcal{D}_{MK}^I + (-1)^{I+K} \xi_{\bar{K}} \mathcal{D}_{M-K}^I]. \quad (55)$$

B. Next-to-leading order

The first-order correction to the adiabatic picture is generated by the NLO piece of the effective Hamiltonian. This term is linear in v and couples the angular velocity of the system to the fermions degrees of freedom. It has a similar form to the well-known Coriolis coupling of classical mechanics. The expectation value of the NLO Hamiltonian, $\hat{H}_{\text{NLO}} = \hat{H}_{\text{LO}} + \Delta \hat{H}_{\text{NLO}}$, for states in a K band is

$$E_{\text{NLO}}(I, K) = A_{\text{rot}} I(I+1) + \tilde{E}_K + A_1 (-1)^{I+1/2} \left(I + \frac{1}{2} \right) \delta_K^{1/2}. \quad (56)$$

Here we have absorbed all corrections to the fermion's energy into \tilde{E}_K , and defined the LEC $A_1 \equiv -a\hbar C_1/2C_0$, with $a = -\langle K=1/2 | \sqrt{2} \hat{J}_{+1} | K=1/2 \rangle$ being Bohr and Mottelson's decoupling constant (notice the difference in the convention for \hat{J}_{+1}). This yields the expectation that the LEC A_1 is of order A_{rot} times the single-particle J . In this work we do not calculate a since we are agnostic regarding the dynamics in H_{int} . Instead we absorb this matrix element in the LEC A_1 and fit it to data.

The NLO correction to the energies is zero for all bands with $K \neq 1/2$ since $\Delta \hat{H}_{\text{NLO}}$ changes K by one unit. The last term in $E_{\text{NLO}}(I, K)$ is sometimes called the signature term, and it causes staggering between adjacent states in $K = 1/2$ bands. This staggering is clearly visible in experimental data. Thus, the addition of the NLO correction to the energies should improve the description of $K = 1/2$ bands.

We note that the Coriolis-like term in H_{NLO} can be treated in perturbation theory because we assume that the splitting between the $K = 1/2$ and $K = 3/2$ band (say) is large compared to the shift in energy induced by the NLO Hamiltonian. This provides a criterion for when this NLO term should be treated non-perturbatively. If the difference of band-head energies becomes of order ΔE_{NLO} then ΔH_{NLO} must be diagonalized in the basis of states $|\pm K\rangle$ and $|\pm(K+1)\rangle$. The result of this diagonalization is worked out by Papenbrock and Weidenmüller

in Ref. [4] and then employed in ^{187}Os . Here we restrict ourselves to situations where $E_{K+1} - E_K \gg \Delta E_{\text{NLO}}$ and so perturbation theory is applicable.

C. Next-to-next-to-leading order

At next-to-next-to-leading order (N²LO) we should in principle consider two insertions of the Coriolis-like operator (42). This second-order correction accounts for virtual excitations of the fermion from, for example, a $K = 1/2$ band to a $K = 3/2$ band and back to the $K = 1/2$ band. The calculation of these effects is discussed in Ref. [1]. However, in an EFT in which only one fermionic state is a low-energy degree of freedom there are no states to sum over in the second-order perturbation theory calculation. All such second-order effects are “high-energy physics” and, as such, get subsumed into the operators that appear in the N²LO Hamiltonian, $\hat{H}_{\text{N}^2\text{LO}} = \hat{H}_{\text{NLO}} + \Delta \hat{H}_{\text{N}^2\text{LO}}$. In particular, the first term in Eq. (44) has the same operator structure as two insertions of the Coriolis-like operator. We calculate its contribution and that of the second term in Eq. (44) in Appendix B, and rewrite the resulting N²LO shift in the energy as a K -band dependent shift in the LEC A_{rot} , i.e.:

$$\Delta E_{\text{N}^2\text{LO}}(I, K) = \Delta A_K I(I+1), \quad (57)$$

where

$$\Delta A_K \equiv -\frac{\hbar^2}{2C_0^2} \langle KIM | (C_2 \hat{J}_{+1} \hat{J}_{-1} + D_2 \hat{J}^2) | KIM \rangle. \quad (58)$$

Taking C_2 and D_2 to be of order E_{sp}^{-1} or E_{vib}^{-1} and \hbar^2/C_0 of order E_{rot} gives us an estimate for $\Delta A_K/A$ of order $\mathcal{O}(\epsilon_{\text{sp}}, \epsilon_{\text{vib}})$. Meanwhile, the contribution to the energy shift from the last term in the operator version of Eq. (44) can be absorbed into a redefinition of the energy \tilde{E}_K of the fermion, since the operator contributes only to H_{ferm} . Hence, the energy formula up to N²LO is

$$E_{\text{N}^2\text{LO}}(I, K) = A_K I(I+1) + \tilde{E}_K + A_1 (-1)^{I+1/2} \left(I + \frac{1}{2} \right) \delta_K^{1/2}. \quad (59)$$

This appears to be the same as E_{NLO} . However, A_K includes ΔA , which depends on fermionic matrix elements. This means we should fit A_K to the odd-mass system. We find that A_K tends to be smaller than A_{rot} for ground-state bands. This is expected if ΔA_K is dominated by the piece $\sim C_2$, since second-order perturbations to a ground-state energy will result in a change in A in this direction [1].

D. N³LO

The pattern continues at N³LO. The first operator in Eq. (46) has the operator structure of three insertions of

FIG. 1. Calculated energies for the $1/2^-$ ground-state rotational band in ^{169}Er . The black line shows experimental values taken from the NNDC [25]. Red triangles, green squares, cyan diamonds, blue pentagons and magenta circles show calculated energies at LO, NLO, $N^2\text{LO}$, $N^3\text{LO}$, and $N^4\text{LO}$, respectively. The right panel is a continuation of the left panel with a different scale for the y-axis.

the Coriolis operator, but since no other states in the theory are dynamical, the sum over other states is replaced by an overall constant $C_3/3C_0^3$. This operator permits the $K = 3/2$ band to couple to itself thereby producing a signature term for the energies of $K = 3/2$ states. Meanwhile, the Coriolis-like operator that gave rise to the signature term in $K = 1/2$ bands at NLO is itself modified through multiplication by a factor of \hat{Q}^2 . Thus, the energy formula at $N^3\text{LO}$ takes the form

$$\begin{aligned}
 E_{N^3\text{LO}}(I, K) = & A_K I(I+1) + \tilde{E}_K \\
 & + A_1(-1)^{I+1/2}(I+1/2)\delta_K^{1/2} \\
 & + B_1(-1)^{I+1/2}I(I+1)\left(I+\frac{1}{2}\right)\delta_K^{1/2} \\
 & + A_3(-1)^{I+3/2}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\delta_K^{3/2}.
 \end{aligned} \tag{60}$$

Since these effects occur at $N^3\text{LO}$, we expect B_1/A_{rot} and A_3/A_{rot} to be of order $(\epsilon_{\text{sp}}, \epsilon_{\text{vib}})^2$.

E. $N^4\text{LO}$

Including the operators in Eqs. (48) and (50) yields the $N^4\text{LO}$ energy formula

$$\begin{aligned}
 E_{N^4\text{LO}}(I, K) = & A_K I(I+1) + \tilde{E}_K \\
 & + A_1(-1)^{I+1/2}(I+1/2)\delta_K^{1/2} \\
 & + B_1(-1)^{I+1/2}I(I+1)\left(I+\frac{1}{2}\right)\delta_K^{1/2} \\
 & + A_3(-1)^{I+3/2}\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\delta_K^{3/2} \\
 & + B_K I^2(I+1)^2,
 \end{aligned} \tag{61}$$

where we defined $B_K \equiv B_{\text{rot}} + \Delta B_K$, with B_{rot} and ΔB_K resulting from the contributions in Eqs. (50) and (48), respectively. We note that $B_{\text{rot}} \sim E_{\text{rot}}\epsilon_{\text{vib}}^2$ while $\Delta B_K \sim$

$E_{\text{rot}}\epsilon_{\text{sp}}^3$. As mentioned above, these two are of roughly the same size for the nuclei studied in this work. We therefore assign both effects to $N^4\text{LO}$ in our EFT. The difference between B_K and B_{rot} tends to be much larger (in fractional terms) than that between A_K and A_{rot} .

Before closing this section we point out that the formulae (61) and (59) can both be applied to bands with $K = 5/2, K = 7/2$, etc. It is just that, up to the order we work here, staggering is absent for bands with $K \geq 5/2$, and so the only terms that are present are the ones with even powers of I . Note that the assumption that matrix elements of the fermion angular momentum operator are ~ 1 becomes increasingly questionable as K increases.

VI. APPLICATION

We show the bandhead state properties, relevant energy scales, and ratios of low-energy constants (LECs) for the systems ^{99}Tc , ^{159}Dy , $^{167,169}\text{Er}$, $^{167,169}\text{Tm}$, ^{183}W , ^{235}U and ^{239}Pu in Table II. In the “Energy Scales” part of the table E_{rot} is taken to be the energy of the first 2^+ state in the ground-state rotational band of the rotor. The energy scale of vibration, E_{vib} , is the energy of the first vibrational energy level of the rotor, and E_{sp} is the difference in energy between the energy of the specific band we are looking at and the next band that couples with it with $|\Delta K| \leq 1$. We see a clear trend that ϵ_{vib} decreases with increasing mass. However, ϵ_{sp} doesn’t seem to have a clear trend. The results in the table for LEC ratios are discussed below, in Sec. VI G.

Here we will, though, briefly describe the procedure we used to fit the LECs in the energy formula for $K = 1/2$ bands. At LO, the LECs A_{rot} and \tilde{E}_K are fitted to the energies of the 2^+ state in the ground-state rotational band of the rotor and the bandhead of the $K = 1/2$ rota-

tional band under consideration, respectively. At NLO, the LECs \tilde{E}_K and A_1 are fitted to the energies of the first two states of the $K = 1/2$ band, while the LEC A_{rot} is still fitted to the rotor. Starting at N²LO, all the LECs in the energy formula are fitted to the energies of the lowest states of the $K = 1/2$ band.

For $K = 3/2$ bands, we employ the lowest states in the considered band to fit the parameter E_K in the energy formula at LO. At NLO there is no correction to the energy of the $K = 3/2$ band. At N²LO and beyond, $K = 3/2$ bands are described in terms of the rotor's effective moment of inertia and the energy of the bandhead. At N²LO band-dependent terms shift the LEC A_{rot} , effectively changing the moment of inertia. At N³LO the signature term proportional to I^3 produces the dominant energy staggering in these bands. That staggering is typically less pronounced than that observed in $K = 1/2$ bands, in agreement with our power counting.

For bands with $K \geq 5/2$ staggering terms are absent up to N⁴LO. This leaves us with only three coefficients to determine. At LO we fit the LEC A to the rotor's spectrum and at N²LO and N⁴LO we fit all our LECs to low-lying levels in the odd nucleus. Tables III, IV and V list the LECs employed at each order to describe the bands considered in this work.

A. Poster children: $K = 1/2$ bands in ^{167}Tm and ^{169}Er

For the description of the $1/2^-$ and $1/2^+$ ground-state rotational bands of ^{169}Er and ^{167}Tm we use ^{168}Er and ^{166}Er as rotors, respectively. Figures 1 and 2 show the calculated energies of these bands up to N⁴LO together with experimental data. In Figures 3 and 4 the absolute residuals between theory and experiment, $|E_{\text{theo}} - E_{\text{exp}}|$, are plotted as a function of the total angular momentum of the system, I , on a log-log plot. To gain insight as to how the error in our calculations scales with I , we remove the staggering of the absolute residuals, clearly seen in the log-log plots, by averaging the residuals of each pair of neighboring levels. This yields the solid lines in Figs. 3 and 4. If the error scales with a definite power of I , as expected in our EFT, these averaged residuals should follow a straight line with a slope greater than or equal to that power in the log-log plots. The slope of the line that best fits the averaged residuals is given in these figures' legends.

For ^{169}Er and ^{167}Tm , the log-log plots make evident the systematic improvement of the calculated energies. Going from LO to NLO removes the energy staggering seen at LO (red triangles). Refitting the moment of inertia at N²LO yields a clear improvement over NLO, as it permits the removal of errors of order I^2 . This increases the slope of the averaged residuals significantly and gives us better agreement with experiment. However, N²LO calculations reveal that there is staggering at higher orders which cannot be removed by the (NLO)

signature term, proportional to I . Adding the correction to this term proportional to I^3 at N³LO, removes most of this higher-order staggering. In ^{167}Tm , the N³LO energy formula gives us better qualitative agreement with experiment. However, the averaged error increases slightly as signaled by the decrease in the slope of the averaged residuals. For ^{169}Er , the staggering is not clearly removed at N³LO but the slope of the average residuals increases. Finally adding the N⁴LO correction to the energy formula, proportional to I^4 , improves the agreement with experiment dramatically, increasing the slope of the averaged residuals. We therefore see systematic order-by-order improvement across the known rotational levels of the ground-state bands of ^{169}Er and ^{167}Tm . The increasing slopes of the residuals make evident that the theory will eventually break down at higher I . Indeed, we already almost see this breakdown at the highest known levels.

There is similar systematic improvement for ^{169}Tm but fewer levels so we do not discuss this case in the main text. Plots for that case which correspond to Figs. 2 and 4 are provided in Appendix C. ^{167}Er based on a ^{166}Er core behaves similarly to ^{169}Er , but there is less staggering. We discuss ^{167}Er below, in Section VID, where we demonstrate that our EFT can describe multiple rotational bands in the same nucleus. The similarity of the results for ^{169}Tm and ^{167}Er to the cases presented in this section is not surprising given that the energy scales in all four systems are very similar.

B. More complicated, yet still successful cases: $K = 1/2$ bands in ^{239}Pu

The case of ^{239}Pu is more complicated as there are more single-particle levels close together. A variant of the EFT presented in this work was already successfully applied to ^{239}Pu in Ref. [4]. There ^{238}Pu was chosen as the rotor, and we make the same choice. We study the rotational band built on the $1/2^+$ ground state, and carry out the analysis up to N⁴LO. Figure 5 shows a clear systematic improvement in the agreement with data as we go to higher orders. Moving to the residuals, Fig. 6 shows good order-by-order improvement both in the size of residuals and in removal of the energy staggering. The slopes of the lines that best fit the averaged residuals in this plot increase as expected going from NLO to N²LO and from N³LO to N⁴LO.

Papenbrock and Weidenmüller [4] chose the energy of the $5/2^+$ bandhead at 300 keV as the breakdown scale in ^{239}Pu . We instead take $E_{\text{sp}} = 752$ keV since this is the energy of the first bandhead above the $1/2^+$ band with $|\Delta K| \leq 1$ and so sets the scale for mixing with the $1/2^+$ at N²LO. We find the scales of the LECs are consistent with our power counting and this choice of E_{sp} . ΔA could be considered an exception to this statement, but this somewhat large shift in A at N²LO can be understood in terms of the Nilsson model. There we expect the fermion

FIG. 2. Calculated energy for the $1/2^+$ ground-state rotational band in ^{167}Tm . The black line shows the experimental values taken from the NNDC [26]. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The right panel is a continuation of the left panel with a different scale for the y-axis.

to be in a large j orbital which increases the size of the Coriolis coupling.

C. $K = 3/2$ bands too: ^{159}Dy

To assess the EFT's performance for $K = 3/2$ bands we need a case where there is a significant amount of data on the band's energy levels, and where other bands for which $|\Delta K| \leq 1$ are separated by appreciable energy gaps from the band of interest. ^{159}Dy , where the ground state

has $I = 3/2$, provides such a case. For this band there is clear systematic improvement as shown in Fig. 7 and Fig. 8. From LO to N^2LO the slope of the residuals in the log-log plot increases by more than two units. From N^2LO to N^3LO the energy staggering (proportional to I^3) is almost completely removed. Finally, at N^4LO the slope improves to 5–6, consistent with the idea that it is I^5 staggering and an I^6 term that are the dominant omitted effects.

FIG. 3. Energy residuals for the $1/2^-$ ground-state rotational band in ^{169}Er on a log-log scale. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.

FIG. 4. Energy residuals for the $1/2^+$ ground-state rotational band in ^{167}Tm on a log-log scale. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.

FIG. 5. Calculated energy for the $1/2^+$ ground-state rotational band in ^{239}Pu . The black line shows the experimental values taken from the NNDC [27]. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the calculated energies at LO, NLO, $N^2\text{LO}$, $N^3\text{LO}$, and $N^4\text{LO}$ respectively. The right panel is a continuation of the left panel with a different scale for the y-axis.

FIG. 6. Energy residuals for the $1/2^+$ ground-state rotational band in ^{239}Pu on a log-log scale. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, $N^2\text{LO}$, $N^3\text{LO}$, and $N^4\text{LO}$ respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.

D. Multiple well-separated bands: ^{167}Er and ^{235}U

Our EFT can be applied to multiple bands in the same nucleus. The formulae we have derived apply simultaneously to two bands if:

1. the inter-band spacing, which will typically be $\sim E_{\text{sp}}$ is large compared to the intra-band spacing which is $\sim E_{\text{rot}}$; or
2. the bandhead states have different parity, and so do not mix; or

3. the bandheads have values of K that differ by 2 or more and so do not mix up to $N^4\text{LO}$.

If any of these conditions are satisfied inter-band mixing can be neglected. The energy levels in the two bands then are each governed by the formulae (59) and (61), with different coefficients in the formulae applying for the two different bands. However, the assumption that matrix elements of the angular-momentum operator between single-particle wave functions is of order 1 is weakened when we consider rotational bands built on band-head states of larger K . This means that we expect more systematic order-by-order behavior in the EFT for, e.g., the $K = 1/2$ bands.

For ^{235}U we consider ^{234}U to be our rotor. We study the rotational bands built on top of the $7/2^-$ ground state and the $1/2^+$ and $5/2^+$ excited states of ^{235}U . The top-right panel of Fig. 9 shows that the EFT works well for the $1/2^+$, performing similarly to the case of the $1/2^+$ band in ^{239}Pu studied above. The other two panels on the right-hand side of Fig. 9 demonstrate that there is also systematic improvement in the $5/2^+$ and $7/2^-$ bands: the slope of the log-log residual plot increases from LO to $N^2\text{LO}$ and again from $N^2\text{LO}$ to $N^4\text{LO}$. We note that the $7/2^-$ and $1/2^+$ bands are only separated by 76 eV here, but although they are not well separated in energy they are separated in the other senses defined above, and so the EFT describes the energy levels well, i.e., there is no evidence of inter-band mixing. On the left-hand side of the same figure we also see the same systematic improvement for rotational bands built on top of the $7/2^+$ ground state and the $1/2^-$ and $5/2^-$ excited states of ^{167}Er . (Here we consider ^{166}Er to be the rotor.) The EFT predicts that staggering in these $5/2$ and $7/2$ bands occurs only at orders beyond those we've calculated here. Indeed, we don't see clear staggering in three of the four lower panels of Fig. 9. The exception is the $7/2^+$ band

FIG. 7. Calculated energies for states in the $3/2^-$ ground-state rotational band in ^{159}Dy . The black lines show the experimental values taken from the NNDC [29]. The red triangles, cyan diamonds, blue pentagons and magenta circles are the calculated energies at LO, N^2LO , N^3LO , and N^4LO respectively. The right panels are a continuation of the left panels with a different scale on the y-axis.

of ^{167}Er . There, we extracted the rate at which the staggering grows with I in the N^2LO fit and found it to be $\sim I^5$. This is reassuring as it says this staggering effect is indeed higher order than N^3LO .

For both nuclei, we notice that, in the $7/2$ rotational bands, the N^2LO curve does better than the N^4LO at low I . This breakdown of the systematic improvement at low I may be due to the violation of the assumption that matrix elements of \hat{j} between single-fermion states are of order 1.

FIG. 8. Energy residuals for the $3/2^-$ ground-state rotational band in ^{159}Dy on a log-log scale. The red triangles, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, N^2LO , N^3LO , and N^4LO respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.

E. Two nearby bands: ^{183}W

For ^{183}W we study the $1/2^-$ ground-state band and take the LEC A from ^{182}W as our rotor. We use the same procedure we used previously to get our LECs at each order.

The bottom panels of Fig. 10 show the calculated energies for the ground-state band of ^{183}W at all orders together with experimental data. We have to note that for ^{183}W , there exists a low-lying $3/2^-$ state at 208.8 keV which makes $\epsilon_{\text{sp}} = 0.48$. This makes our expansion parameter larger than the usual cases and we expect our EFT to break down relatively quickly. This could be understood in terms of band mixing between the $1/2^-$ and $3/2^-$ bands [5]. A way to fix this would be to include the $3/2^-$ band as an additional low-energy degree of freedom in the Lagrangian. This would require us to fit the two bands simultaneously and we would then expect to get better agreement with data.

This kind of EFT treatment of the rotor-fermion problem was implemented by Papenbrock and Weidenmüller for ^{187}Os [4]. They argued that this provides an EFT definition of triaxiality. Conversely, for rotational states whose excitation energies are less than E_{sp} one can still perturb around the axial limit.

The staggering in ^{183}W is not clearly present in experimental data and therefore we do not see a clear improvement going from LO to NLO. Going to N^2LO we see a clear improvement overall and at N^4LO we only see improvement for the levels with low I . This comes from the relatively large expansion parameter and is consistent with our expectation that the EFT breaks down relatively early.

The right panel of Fig. 11 shows the log-log plot of the residuals where we clearly see the breakdown at around $I = 15/2$, where the N^2LO and N^3LO lines cross the

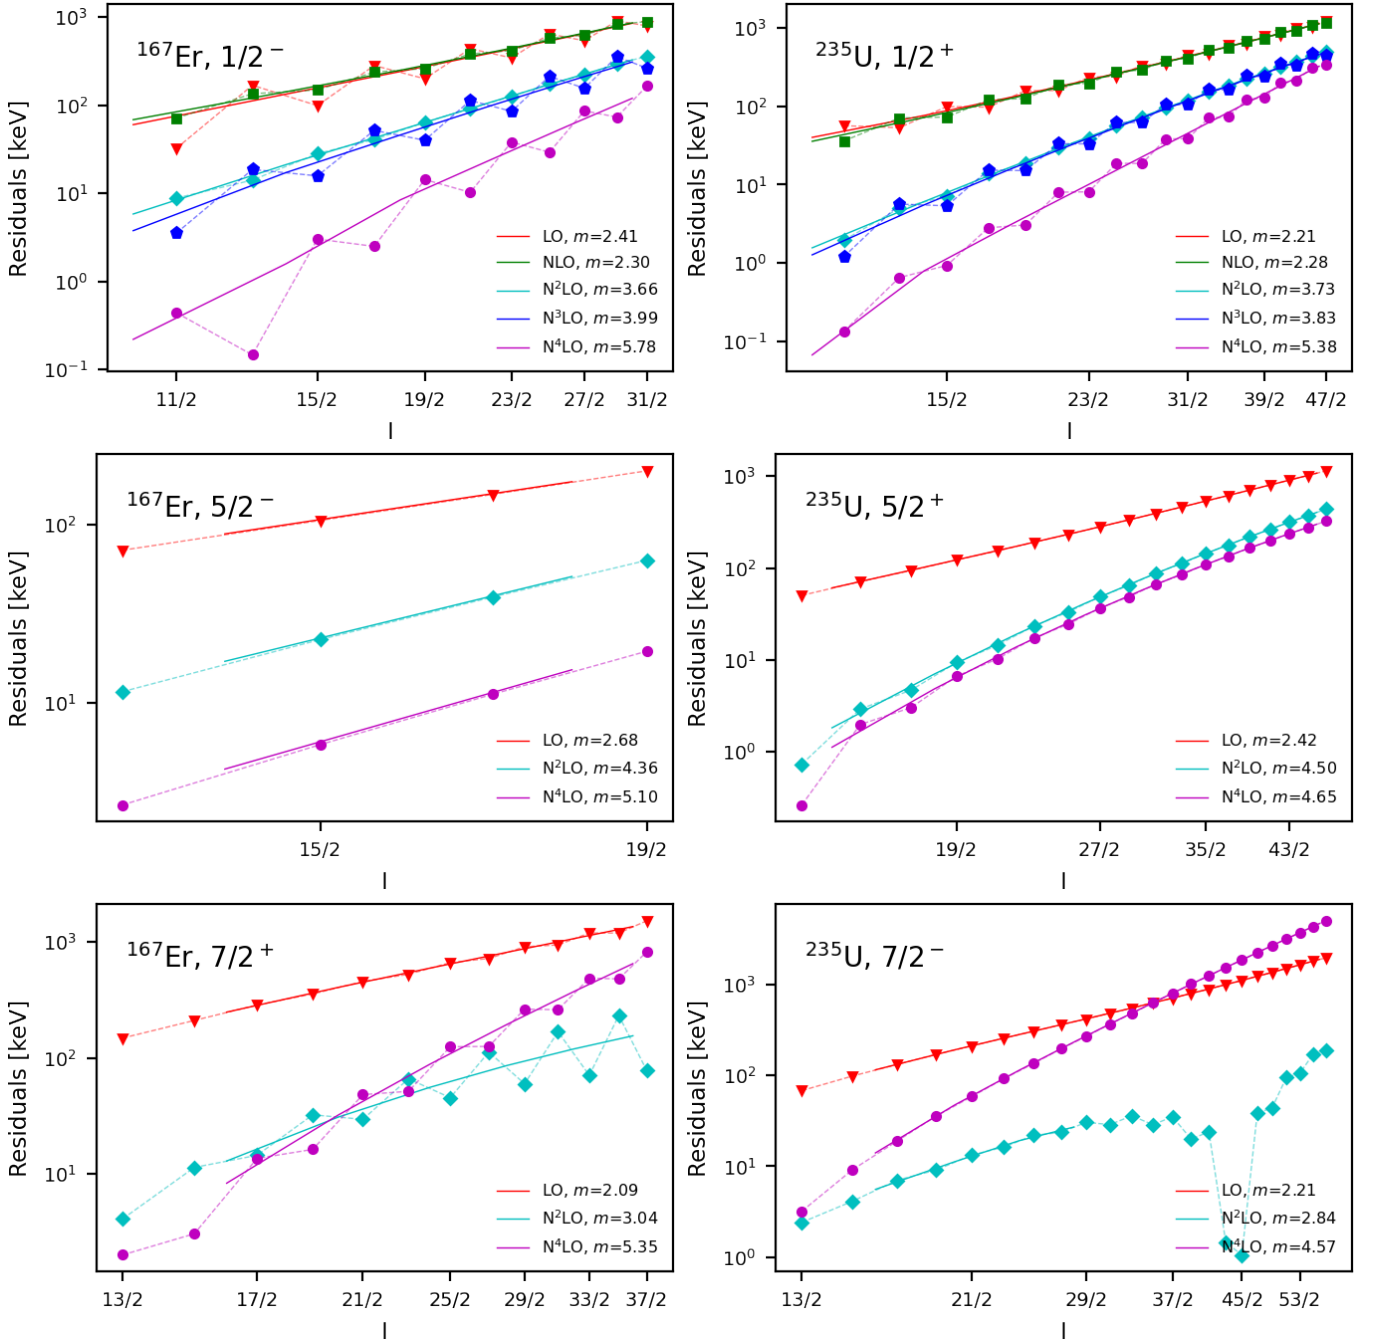

FIG. 9. Energy residuals for the $1/2^-$, $5/2^-$ and $7/2^+$ rotational bands in ^{167}Er (left column) and for the $1/2^+$, $5/2^+$ and $7/2^-$ rotational bands in ^{235}U (right column) on a log-log scale. Experimental values are taken from the NNDC [26, 28]. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines. For the $7/2^-$ rotational band in ^{235}U we see an accidental decrease in the residuals beyond $I = 29/2$ at N^2LO . Therefore we don't include the points beyond $I = 29/2$ when calculating the slope.

N^4LO line. The very low residual at $I \approx 15$ for N^2LO is accidental: the residuals shift from being negative to being positive there. This accidental crossing also explains the bending of the N^2LO and N^3LO lines for $I > 10$.

F. What failure looks like: ^{99}Tc

For ^{99}Tc we look at the rotational band built on top of the first $1/2^-$ excited state. We consider ^{99}Tc to be

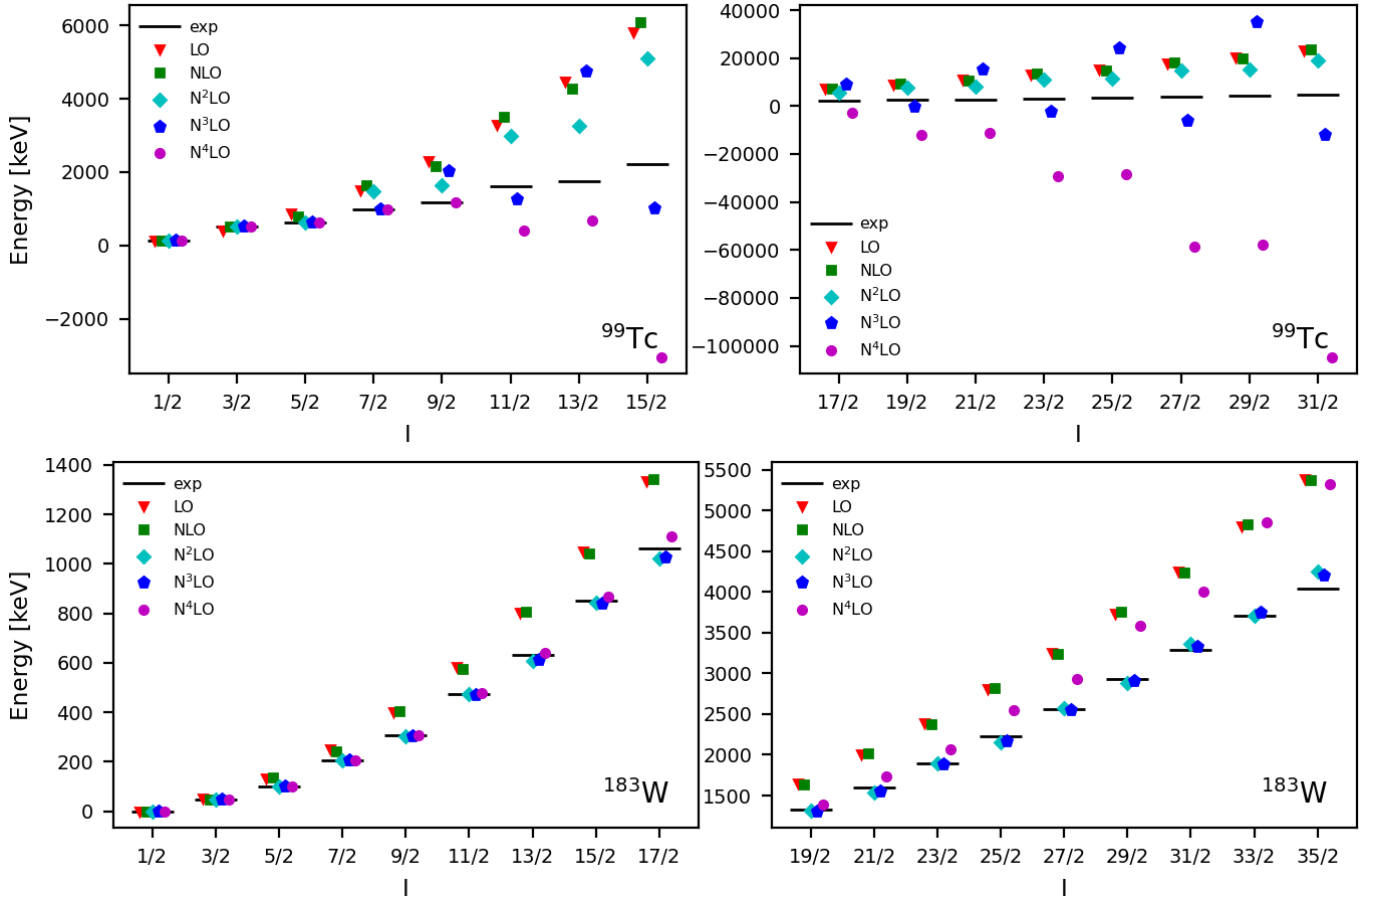

FIG. 10. Calculated energy for states in the $1/2^-$ excited-state rotational band in ^{99}Tc (top panels) and in the $1/2^-$ ground-state rotational band in ^{183}W (bottom panels). The black line shows the experimental values taken from the NNDC [30, 31]. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The right panel is a continuation of the left panel with a different scale for the y-axis.

FIG. 11. Energy residuals for states in the $1/2^-$ excited-state rotational band in ^{99}Tc (top panels) and in the $1/2^-$ ground-state rotational band in ^{183}W (bottom panels) on a log-log scale. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, N^2LO , N^3LO , and N^4LO respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.

a proton hole on top of ^{100}Ru as the rotor. We expect the breakdown scale for ^{99}Tc to be very low since ϵ_{sp}

is greater than 1. We clearly see this in the top panels in Fig. 10 and the left panel in Fig. 11, where going to higher order doesn't necessarily describe the data better. In fact, at $N^4\text{LO}$ the theory prediction does worse than the predictions at lower orders when we go beyond the $17/2^-$. Indeed, apart from the levels used in the fit, we could describe the energies of all levels better at lower orders. We also do not see the expected increase in the slope going from NLO to $N^2\text{LO}$. The magenta line crossing all the other lines in figure 11 at low energies is a quantitative measure of the low breakdown energy of the fermion-rotor EFT in this case.

G. Values and order-by-order stability of LECs

We show the bandhead properties, relevant energy scales, and the relative sizes of LECs for the systems studied in this work in Table II. The third, fourth, and fifth segments of the table show the relative size of the LEC that appears at that order compared to the LO LEC A . Each block then compares that relative size to the expectation based on energy-scale ratios in the nucleus of interest. We note that it is sometimes hard to decide whether ϵ_{sp} or ϵ_{vib} sets the size of the correction at each order and indeed, one sometimes sees an interplay between both. The ratios fall in the expected range except for a few cases. For ^{239}Pu ($1/2$ band in ^{235}U) we see that $\Delta A/A$ is two times (1.5 times) larger than both ϵ_{sp} and ϵ_{vib} . This is consistent with natural coefficients in the EFT expansion. It could be related to the large Coriolis coupling associated with high j orbitals for the fermion. ^{239}Pu and ^{235}U are large nuclei and we expect the intrinsic wave functions for both nuclei to have sizable intrinsic angular momentum for the last nucleon. High j orbitals also cause the size of the corrections for the $5/2$ and $7/2$ bands to be larger than expected for the two nuclei where we considered multiple bands. One interesting observation in those nuclei is that we see similar sized corrections for the bands with the same parity. This is consistent with the assumption that the odd fermion does not occupy a single j orbital, but instead, multiple j orbitals with the same parity and projection K contribute to the fermionic wave function. We also notice two nuclei where E_{sp} is comparable to E_{rot} , ^{99}Tc and ^{183}W . In those two cases we expect the breakdown scale to be very low and our EFT not to be very useful.

In Table III we show, for each of the nuclei whose $K = 1/2$ bands we have studied in this work, the values of the LECs obtained at each order. For the nuclei where we have a good separation of scales we see that the LECs are stable going from order to order. Since we take A from the rotor at LO and at NLO, it only changes at $N^2\text{LO}$ where we re-fit the moment of inertia. The size of change for A is consistent with the power counting, as shown in Table II and discussed in the previous paragraph.

The A_1 parameter also changes when going from NLO to $N^2\text{LO}$ and then stabilizes for nuclei with good separa-

tion of scales. The sizable change is because we remove the I^2 dependence when we fit the A parameter to the odd mass system at $N^2\text{LO}$. Until that happens A_1 is contaminated by $\sim I^2$ effects. For ^{183}W we see a large shift in A_1 going from NLO to $N^2\text{LO}$, but this is because there is no clear staggering in the experimental data for this nucleus. ^{99}Tc has the largest fluctuations in all its LECs because of the large expansion parameter $\epsilon_{\text{sp}} > 1$.

We note that B is negative for most $K = 1/2$ bands. This can be understood from the rigid rotor model where when we allow for small fluctuations around rigidity the moment of inertia increases with increasing I , due to centrifugal distortions.

Table IV provides the LECs for the nuclei where we examined data on a $K = 3/2$ band. As in the studied $K = 1/2$ bands, the change in A from LO to $N^2\text{LO}$ is consistent with expectations from the power counting. The values for this LEC at higher orders do not change drastically. The variation of the LEC that enters at $N^3\text{LO}$ and accompanies the $K = 3/2$ signature term, A_3 , with the EFT order is similar to that of B_1 .

Table V provides the LECs for the two nuclei where we examined $5/2$ and $7/2$ bands. Here only LECs associated with even orders appear, since the EFT predicts there is no staggering at $N^4\text{LO}$ for $5/2$ and $7/2$ bands.

H. Extracting the breakdown scale in different systems

We extract the breakdown scale by locating where the $N^4\text{LO}$ line (magenta) crosses the lower-order lines in the log-log plots. That is to say: we define the theory to have broken down when the theory prediction at $N^3\text{LO}$ does better than the prediction at $N^4\text{LO}$. This occurs within the range of the plot for ^{99}Tc and ^{183}W , where we identify the breakdown scale to be at 1500 keV and 820 keV respectively. We note that these numbers are higher than the naive breakdown scale associated with other single-particle energies. We see a similar higher-than-expected breakdown scale for the other nuclei considered. For the $7/2$ bands in ^{235}U and ^{167}Er we see the breakdown happening at about 200 keV and 1000 keV respectively. The lower than expected breakdown scale for the $7/2$ band in ^{235}U is puzzling. In fact, it's only for ^{99}Tc , ^{183}W and the $7/2$ bands in ^{235}U and ^{167}Er that the $N^4\text{LO}$ line even crosses the lower order line. In other nuclei the $N^4\text{LO}$ line does not cross the $N^3\text{LO}$ line within the domain of levels considered in this study, even though we go well beyond the single-particle and vibrational energy scales.

VII. SUMMARY AND OUTLOOK

In their 1969 book Bohr and Mottelson give a formula for the energies of rotational bands in odd-mass nuclei and explain how that formula arises from the particle-rotor model. In this work we have shown how this de-

Nucleus	Bandhead		Energy scales [keV]			N ² LO			N ³ LO			N ⁴ LO		
	E [keV]	J^π	E_{rot}	E_{vib}	E_{sp}	$\Delta A/A$	ϵ_{sp}	ϵ_{vib}	$(B_1, A_3)/A$	$(\epsilon_{\text{sp}})^2$	$(\epsilon_{\text{vib}})^2$	B/A	$(\epsilon_{\text{sp}})^3$	$(\epsilon_{\text{vib}})^2$

TABLE II. In the first block of the table we show the rotational bandhead energy, spin and parity. In the second block energy scales for different nuclei are shown in units of keV. In the third block we compare the relative correction to A at N²LO, $\Delta A/A$, to its expected size $\epsilon_{\text{sp}}, \epsilon_{\text{vib}}$. In the next block, B_1/A (or A_3/A for 3/2 bands) is the relative correction to the energy at N³LO; its expected size is $(\epsilon_{\text{sp}}, \epsilon_{\text{vib}})^2$. Finally, at N⁴LO the relative correction is B/A and this is expected to be of order $(\epsilon_{\text{sp}})^3$ or $(\epsilon_{\text{vib}})^2$. Multiple bands within the same nucleus are grouped in the same block.

Nucleus	A [keV]					A_1 [keV]				B_1 [keV]		B [keV]
	LO	NLO	N ² LO	N ³ LO	N ⁴ LO	NLO	N ² LO	N ³ LO	N ⁴ LO	N ³ LO	N ⁴ LO	N ⁴ LO

TABLE III. The different LECs at each order for $K = 1/2$ bands. Note that going from NLO to N²LO we do not add a new LEC, however at LO and NLO we fit A to the the rotational band in the rotor, while at N²LO and beyond we fit A to the band in the odd-mass nucleus.

Nucleus	A [keV]				A_3 [keV]		B [keV]
	LO	N ² LO	N ³ LO	N ⁴ LO	N ³ LO	N ⁴ LO	N ⁴ LO
¹⁶⁷ Er	13.43	8.44	8.80	8.69	-0.059	-0.054	0.007
¹⁵⁹ Dy	16.48	11.32	11.35	11.44	-0.005	-0.009	-0.005

TABLE IV. The different LECs at each order for $K = 3/2$ bands. Note that going from LO to N²LO we do not add a new LEC. However at LO we fit A to the the rotational band in the rotor, while at N²LO and beyond we fit A to the band in the odd-mass nucleus.

Nucleus	J^π	A [keV]			B [keV]
		LO	N ² LO	N ⁴ LO	N ⁴ LO
¹⁶⁷ Er	5/2 ⁻	13.43	11.92	11.92	-0.011
	7/2 ⁺	13.43	8.81	8.81	0.008
²³⁵ U	5/2 ⁺	7.25	6.01	6.01	-0.0004
	7/2 ⁻	7.25	5.12	5.12	0.007

TABLE V. The different LECs at each order for $K = 5/2$ and $K = 7/2$ bands. Note that going from LO to N²LO we do not add a new LEC. However at LO we fit A to the the rotational band in the rotor, while at N²LO and beyond we fit A to the band in the odd-mass nucleus.

scription of rotational bands in odd-mass nuclei that are built on a single fermion level can be understood as an effective field theory (EFT). The expansion parameter in the EFT is v , the rotational velocity of the system. The expansion in v in the Lagrangian becomes a dual expansion in powers of ϵ_{sp} and ϵ_{vib} in the Hamiltonian and for the band's energy levels. We worked out the energy-level formula to fourth order in this expansion and fitted the parameters therein for the systems ^{167,169}Tm, ^{167,169}Er, ²³⁹Pu, ²³⁵U, ¹⁵⁹Dy, ⁹⁹Tc, and ¹⁸³W. The EFT gives a

good description of rotational energy bands to surprisingly high spin in the first seven cases, but fails in the last two. The results in ¹⁶⁷Er and ²³⁵U show that the energy-level formula can be successfully applied to multiple bands in a given nucleus as long as those bands are well-separated in energy and/or K or they are of opposite parity.

We showed that this EFT viewpoint on rotational

bands in odd-mass nuclei can help to explain why the particle-rotor model works where it does and predict its accuracy in a particular system. Through analysis of both the EFT's low-energy constants and its order-by-order residuals we showed for these nine systems that the size of different effects in the energy-level formula is in line with the power counting in the EFT. The EFT's accuracy in a particular nucleus is connected to the underlying energy scales there.

Our study therefore goes beyond the related discussion of an EFT for rotational bands in odd-mass nuclei by Papenbrock and Weidenmüller in Ref. [4]. That work considered effects up to N²LO in v , and discussed only two different nuclides, ²³⁹Pu and ¹⁸⁷Os. It also did not perform an order-by-order analysis of residuals with respect to data to demonstrate systematic improvement. Moreover, our EFT has a conceptual difference to that of Ref. [4]. Papenbrock and Weidenmüller implicitly assumed that operators in the EFT could also be organized in powers of the fermionic degrees of freedom K , \vec{j} , and \vec{r} . Here we make no such assumption.

That is because we want our results to be independent of the model of the underlying nuclear dynamics. In a particular model of fermionic orbitals, e.g., the Nillson model, some of the low-energy constants appearing in our EFT's Hamiltonian could be predicted. While we agree that they can be estimated, we argue that there are too many unknowns for any particular single-particle model to give a reliable prediction for the EFT coefficients. And indeed, there is a long and not particularly successful string of efforts to explain in the particle-rotor picture why the Coriolis coupling tends to be overestimated once a specific model for the single-particle orbitals is adopted (see, e.g., Ref. [36] for a summary). The most conservative path forward is thus to fit the EFT's formula to data. Connecting the coefficients in the rotational-band formula to the underlying dynamics could be an interesting subject for future work although

it should be noted that an incredible amount of effort has been spent in this direction in the past.

A straightforward next step now that we have an EFT Lagrangian that is a good description of fermionic rotational bands is to include electromagnetic fields and compute intra-band transitions. In even-even nuclei that step generates parameter-free predictions at leading-order accuracy [3]. Another avenue for future work is to use Bayesian parameter estimation to obtain the parameters in the EFT at each order [32–34]. In this work the EFT's coefficients were obtained using the lowest energy levels and assuming no theoretical uncertainty. The Bayesian methodology of Refs. [32–34] ensures that EFT parameters are stable as more orders are included in the fit, because it includes the effects of higher-order terms on those parameters. Finally, we point out that a longer-term goal is to apply this EFT to halo nuclei in which low-lying rotational states of the core play a prominent role, such as ¹¹Be and ³¹Ne. In such an application the fermionic dynamics—or at least part of it—could be explicitly calculated in Halo EFT [35].

ACKNOWLEDGMENTS

DRP is grateful for the warm hospitality of the IKP Theoriezentrum Darmstadt, where part of this work was carried out. We thank Mark Caprio and Thomas Papenbrock for useful discussions. This work was supported by the US Department of Energy, contract DE-FG02-93ER40756 (IKA, DRP), by the ExtreMe Matter Institute (DRP), by the Deutsche Forschungsgesellschaft under Grant SFB 1245 (EACP), and under the auspices of the US Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 (EACP). IKA Acknowledges the support of King Saud University and the Ministry of Education in Saudi Arabia.

Appendix A: Expectation Value of the NLO Hamiltonian

The expectation value of the shift in the Hamiltonian at NLO is

$$\begin{aligned} \langle KIM | \Delta \hat{H}_{\text{NLO}} | KIM \rangle &= \frac{C_1}{C_0} \langle KIM | (\hat{J}_{+1} \hat{Q}_{-1} + \hat{J}_{-1} \hat{Q}_{+1}) | KIM \rangle \\ &= \frac{2C_1}{C_0} \langle KIM | \hat{J}_{+1} \hat{Q}_{-1} | KIM \rangle \end{aligned} \quad (\text{A1})$$

Applying \hat{Q}_{-1} to Ψ_{KIM} gives us

$$\hat{Q}_{-1} \Psi_{KIM} = \frac{\hbar}{\sqrt{2}} \sqrt{\frac{2I+1}{16\pi^2}} \left[\xi_K \sqrt{I(I+1) - K(K+1)} \mathcal{D}_{M(K+1)}^I + (-1)^{I+K} \xi_{\bar{K}} \sqrt{I(I+1) + K(-K+1)} \mathcal{D}_{M(-K+1)}^I \right] \quad (\text{A2})$$

Then we have

$$\begin{aligned}\langle KIM|\Delta\hat{H}_{\text{NLO}}|KIM\rangle &= \frac{2C_1}{C_0}\sqrt{\frac{2I+1}{16\pi^2}}\int d\Omega [\xi_K^*\mathcal{D}_{MK}^{*I} + (-1)^{I+K}\xi_K^*\mathcal{D}_{M-K}^{*I}] \hat{J}_{+1}\hat{Q}_{-1}\Psi_{KIM} \\ &= \frac{2\hbar C_1}{\sqrt{2}C_0}(-1)^{I+K}\left(\frac{2I+1}{16\pi^2}\right)\xi_K^*\hat{J}_{+1}\xi_{\bar{K}}\int d\omega\mathcal{D}_{MK}^{*I}\sqrt{I(I+1)+K(-K+1)}\mathcal{D}_{M(-K+1)}^I\end{aligned}\quad (\text{A3})$$

The last line is non-zero only when $K = 1/2$ and this gives us

$$\langle 1/2IM|\Delta\hat{H}_{\text{NLO}}|1/2IM\rangle = \frac{\hbar C_1}{2C_0}(-1)^{I+1/2}(I+1/2)\langle 1/2|\sqrt{2}\hat{J}_{+1}|1/2\rangle.$$

Appendix B: N²LO Matrix Elements

We want to calculate

$$\langle KIM|(\hat{J}_{+1}\hat{Q}_{-1} + \hat{J}_{-1}\hat{Q}_{+1})^2|KIM\rangle = \sum_{\nu} |\langle \nu IM|(\hat{J}_{+1}\hat{Q}_{-1} + \hat{J}_{-1}\hat{Q}_{+1})|KIM\rangle|^2. \quad (\text{B1})$$

From equation (A2) and integrating over the Wigner D-matrices we have the following matrix elements

$$\begin{aligned}\langle \nu IM|\hat{J}_{+1}\hat{Q}_{-1}|KIM\rangle &= \frac{\hbar}{4}\left[\delta_{\nu,K+1}\sqrt{I(I+1)-K(K+1)}\langle \nu|\sqrt{2}\hat{J}_{+1}|K\rangle\right. \\ &\quad + (-1)^{I+K}\delta_{\nu,-K+1}\sqrt{I(I+1)-K(K-1)}\langle \nu|\sqrt{2}\hat{J}_{+1}|\bar{K}\rangle \\ &\quad + (-1)^{I+\nu}\delta_{\nu,-K-1}\sqrt{I(I+1)-K(K+1)}\langle \bar{\nu}|\sqrt{2}\hat{J}_{+1}|K\rangle \\ &\quad \left.+ (-1)^{2I+K+\nu}\delta_{\nu,K-1}\sqrt{I(I+1)-K(K-1)}\langle \bar{\nu}|\sqrt{2}\hat{J}_{+1}|\bar{K}\rangle\right]\end{aligned}$$

We also have

$$\begin{aligned}\langle \nu IM|\hat{J}_{-1}\hat{Q}_{+1}|KIM\rangle &= \frac{\hbar}{4}\left[\delta_{\nu,K-1}\sqrt{I(I+1)-K(K-1)}\langle \nu|\sqrt{2}\hat{J}_{-1}|K\rangle\right. \\ &\quad + (-1)^{I+K}\delta_{\nu,-K-1}\sqrt{I(I+1)-K(K+1)}\langle \nu|\sqrt{2}\hat{J}_{-1}|\bar{K}\rangle \\ &\quad + (-1)^{I+\nu}\delta_{\nu,-K+1}\sqrt{I(I+1)-K(K-1)}\langle \bar{\nu}|\sqrt{2}\hat{J}_{-1}|K\rangle \\ &\quad \left.+ (-1)^{2I+K+\nu}\delta_{\nu,K+1}\sqrt{I(I+1)-K(K+1)}\langle \bar{\nu}|\sqrt{2}\hat{J}_{-1}|\bar{K}\rangle\right]\end{aligned}\quad (\text{B2})$$

This gives

$$\langle KIM|(\hat{J}_{+1}\hat{Q}_{-1} + \hat{J}_{-1}\hat{Q}_{+1})^2|KIM\rangle = aI(I+1) + bK^2 + cK \quad (\text{B3})$$

where the coefficients a , b , and c are comprised of the squares of matrix elements of $\hat{J}_{\pm 1}$ between the state $|K\rangle$ and states $|\nu\rangle$ and $|\bar{\nu}\rangle$ with $\nu = |K \pm 1|$.

Appendix C: Additional results: ¹⁶⁹Tm

In Figs. 12 and 13 we provide energy spectra order-by-order and log-log plots of residuals for ¹⁶⁹Tm. These are to be compared to the corresponding results in the main text for ¹⁶⁷Tm.

FIG. 12. Calculated energy for states in the $1/2^+$ excited-state rotational band in ^{169}Tm . The black line shows the experimental values taken from the NNDC [25]. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the calculated energies at LO, NLO, $N^2\text{LO}$, $N^3\text{LO}$, and $N^4\text{LO}$ respectively. The right panel is a continuation of the left panel with a different scale for the y-axis.

FIG. 13. Energy residuals for the $1/2^+$ ground-state rotational band in ^{169}Tm on a log-log scale. The red triangles, green squares, cyan diamonds, blue pentagons and magenta circles are the residuals from the calculated energies at LO, NLO, $N^2\text{LO}$, $N^3\text{LO}$, and $N^4\text{LO}$ respectively. The dashed transparent lines are there to guide the eye. The solid lines show the trend of the calculated residuals after averaging out the signature staggering. The slope shown in the legend is the slope of the solid lines.
