            Measurements of bottomonium production in heavy ion and p+p collisions at the Relativistic
```

Measurements of bottomonium production in heavy ion and p+p collisions at the Relativistic Heavy Ion Collider (RHIC) are presented. The inclusive yield of the three  $\Upsilon$  states,  $\Upsilon(1S+2S+3S)$ , was measured in the PHENIX experiment via electron-positron decay pairs at midrapidity for Au+Au and p+p collisions at  $\sqrt{s_{NN}}=200$  GeV. The  $\Upsilon(1S+2S+3S)\to e^+e^-$  differential cross section at midrapidity was found to be  $B_{\rm ee}d\sigma/dy=108\pm38$  (stat)  $\pm$  15 (syst)  $\pm$  11 (luminosity) pb in p+p collisions. The nuclear modification factor in the 30% most central Au+Au collisions indicates a suppression of the total  $\Upsilon$  state yield relative to the extrapolation from p+p collision data. The suppression is consistent with measurements made by STAR at RHIC and at higher energies by the CMS experiment at the Large Hadron Collider.

#### I. INTRODUCTION

One of the main physics programs in relativistic heavy ion collisions is the study of heavy quarkonia yields, namely charm quark pairs (charmonia) and bottom quark pairs (bottomonia). At zero temperature, the binding energy between the heavy quark and anti-quark  $(Q\bar{Q})$  in these vector mesons may be described by an effective potential consisting of a confining term at large distance and Coulomb-like term at short distance [1].

When the temperature of the medium formed after the collision is higher than a transition temperature  $T_c \approx 170$  MeV, the effective potential between light quark and anti-quark weakens and deconfines the constituent quarks of mesons and baryons. The Quark-Gluon Plasma (QGP) formed can be described as a dense, strongly coupled state of matter which reaches thermalization in less than 1 fm/c [2].

In the QGP medium, the effective color electric potential between Q and  $\bar{Q}$  can be screened by the dense surrounding color charges. This color screening is similar to the Debye screening observed in electromagnetic plasmas [3]. The temperature at which the heavy quark state becomes unbound due to this screening depends on the corresponding binding energy of the state. Because of the large variation in radii between the different heavy quarkonia, they are expected to become unbound at different temperatures.

There are many theoretical calculations which predict the temperature at which each quarkonium state is suppressed by color screening. A compilation of results can be found in [4], including lattice quantum chromodynamics (QCD) [5–15], QCD sum rules [4, 16–20], AdS/QCD [21–24], resummed perturbation theory [25, 26], effective field theories [27, 28], and potential models [15, 29–35]. Figure 1 shows the dissociation temperature range for several quarkonium states as expected from these models. Besides the different techniques used in these calculations, the melting range also depends on the choice of the transition temperature, the use of the internal energy or the free energy of the system for the temperature dependence of the heavy quark potential and the criteria adopted for defining the dissociation point. No cold nuclear matter effects have been considered in these estimations.

A comparison between hydrodynamical model calculations and the PHENIX thermal photon data [36] suggests that the peak temperature of the medium formed at RHIC in central Au+Au collisions at  $\sqrt{s_{_{NN}}} = 200$  GeV lies in the region between 300 and 600 MeV, or 1.8  $T_c$  and 3.5  $T_c$ . The majority of the estimates shown in Fig. 1 indicates that only the ground states, the  $J/\psi$  and  $\Upsilon(1S)$ , remain bound at these temperatures.

PHENIX reported a strong suppression of the  $J/\psi$  yield in central Au+Au collisions compared to binary collision scaling from p+p yields [37, 38]. According to measurements performed in p+p collisions at RHIC,  $(42\pm9)\%$  of the  $J/\psi$  yield comes from  $\chi_c$  and  $\psi'$  decays [39]. The complete suppression of these states in Au+Au collisions can explain only part of the suppression seen for the  $J/\psi$ . There are other possible contributions to  $J/\psi$  suppression and therefore the interpretation of the data is not straightforward. Other mechanisms of suppression include initial and final state cold nuclear matter effects, studied in d+Au collisions by PHENIX [40, 41]. There are also effects that can reduce the suppression. The dissociated charm (and anti-charm) quark can undergo multiple scatterings and recombine with its former partner, once the medium cools down. In addition, the presence of about 6-20 open charm pairs in each central Au+Au collision at RHIC <sup>1</sup>, provides a good chance that the ground state charmonium was formed by coalescence of uncorrelated charm and anti-charm quarks present in the medium [43]. Thus, even if all the initially produced  $J/\psi$ s are dissociated in the QGP medium,  $J/\psi$ s can be re-created at a later stage by the coalescence process.

The probability for creating a bottomonium state through coalescence is quite small at  $\sqrt{s_{\scriptscriptstyle NN}}=200~{\rm GeV}$ , given that only about 0.07  $b\bar{b}$  pairs per central event are produced <sup>2</sup>. Therefore, bottomonium states are a better probe of color screening in Au+Au collisions at RHIC. Figure 1 shows that no lattice QCD or potential model calculation predicts that  $\Upsilon(1S)$  will melt at a temperature lower than around 2  $T_c$ . This is an outcome of the tighter binding energy and smaller radius of the 1S state compared to other quarkonium states. Some calculations suggest the ground state charmonium is dissociated at a temperature close to  $T_c$  [20, 31, 34].

Bottomonia have been measured mostly in the dilepton channel with a branching ratio around 2.5% [45]. Table I lists the fraction of the three  $\Upsilon$  states present in the dilepton spectrum as measured at Fermilab and the Large Hadron Collider (LHC) by E866/NuSea [46], CDF [47], LHCb [48] and CMS [49]. No significant variations on the relative yields have been observed in spite of the broad collision energy range of these experiments or whether the anti-proton was one of the collision particles or not. The ground state  $\Upsilon(1S)$  has many feed-down contributions from excited states. The CDF experiment reported the fraction of these contributions [50], which can be seen in Table II.

Fermilab experiments found no modification of the relative yields in cold nuclear matter as measured in p+d [46] and p+A [51]. The initial state effects on bottomonia production were investigated by E605 [52], E772 [51] and E866/NuSea [46] in p+A collisions at  $\sqrt{s_{NN}}$ =38.8 GeV with targets of <sup>2</sup>H, C, Ca and Fe. The  $\Upsilon$  yields are suppressed by ~5% for incident gluon momentum fraction  $x_2 \sim 0.1$ . The suppression gets stronger for larger  $x_2$ , reaching a level of

This estimation is based on the  $c - \bar{c}$  total cross section reported in [42] and 1000 binary collisions in very central Au+Au events.

<sup>&</sup>lt;sup>2</sup> Estimation based on the total  $b\bar{b}$  cross section published in [44].

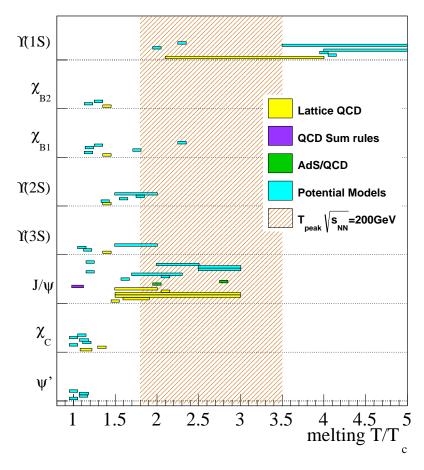

FIG. 1. (Color online) Compilation of medium temperatures relative to the critical temperature  $(T_c)$  where quarkonium states are dissociated in the quark-gluon plasma. Note that these estimations were performed assuming different  $T_c$  values. Each horizontal bar corresponds to one estimation and its temperature extension (when applied) represents the range where the quarkonia state undergoes a mass/size modification until it completely melts. Techniques used in calculations: Lattice QCD [5–15], QCD sum rules [4, 16–20], AdS/QCD [21–24], effective field theories [27, 28] and potential models [15, 29–35]. The shaded band from 1.8 to 3.5  $T/T_c$  represents the hydrodynamic estimation for the peak temperature reached in Au+Au collisions at 200 GeV [36].

TABLE I. Composition of the Υ family in the dilepton channel as measured by E866/NuSea [46], CDF [47], LHCb [48] and CMS [49]. Fractions are in % and only statistical uncertainties are shown.

Exp.	system	$\Upsilon(1S)$	$\Upsilon(2S)$	$\Upsilon(3S)$
		$9.46 \frac{GeV}{c^2}$	$10.02 \frac{GeV}{c^2}$	$10.36 \frac{GeV}{c^2}$
E866	$p+p\sqrt{s}=39 \text{ GeV}$	$69.1 \pm 1.0$	$22.2 \pm 0.9$	$8.8 \pm 0.6$
CDF	$p + \bar{p} \sqrt{s} = 1.8 \text{ TeV}$	$72.6 \pm 2.8$	$17.6\pm1.7$	$9.7 \pm 1.4$
LHCb	$p+p\sqrt{s}=7~{\rm TeV}$	$73.0 \pm 0.3$	$17.9 \pm 0.2$	$9.0 \pm 0.2$
CMS	$p+p\sqrt{s}=7~{\rm TeV}$	$71.6 \pm 1.3$	$18.5\pm0.8$	$10.0 \pm 1.3$

 $^{214}$  ~15% at  $x_2$  ~0.3. PHENIX measured the medium modification of the  $\Upsilon$  family (1S+2S+3S) yield in d+Au collisions at  $\sqrt{s_{NN}}=200$  GeV [53]. The result is consistent with no modification within the large statistical uncertainties at  $x_2 \sim 10^{-2}$  and presents an one standard-deviation suppression at  $x_2 \sim 0.2$ , which is consistent with the Fermilab results and the STAR experiment at midrapidity in d+Au collisions [54]. The RHIC results can be accounted for by a combination of initial state effects, calculated by the parton modification function EPS09 [11], and quarkonium breakup when crossing the cold nuclear matter.

QGP effects on  $\Upsilon$  production were studied at the LHC by the CMS experiment [55] using Pb+Pb collisions at  $\sqrt{s_{NN}}$ =2.76 TeV. The excited state  $\Upsilon(2S)$  is more suppressed than the  $\Upsilon(1S)$  and the  $\Upsilon(3S)$  state is not seen in

TABLE II. Feed-down fractions of the  $\Upsilon(1S)$  state in p+p collisions as measured by CDF for  $p_T > 8 \text{ GeV}/c$  [50].

Source	fraction $\pm$ stat $\pm$ syst
Direct $\Upsilon(1S)$	$0.509 \pm 0.082 \pm 0.090$
$\Upsilon(2S)$	$0.107 \pm 0.077 \pm 0.048$
$\Upsilon(3S)$	$0.008 \pm 0.006 \pm 0.004$
$\chi_{ m B1}$	$0.271 \pm 0.069 \pm 0.044$
$\chi_{ m B2}$	$0.105 \pm 0.044 \pm 0.014$

CMS data. This is qualitatively consistent with expectations of the effects of color screening from several models discussed earlier. The question which arises is whether or not the suppression also happen at lower energies and in an environment with a much smaller number of bottom quarks present in the medium.

This paper reports the measurement of the inclusive  $\Upsilon$  (1S+2S+3S) yield at |y| < 0.35 in Au+Au collisions at  $\sqrt{s} = 200$  GeV. Section II describes the experimental apparatus and the data sample used in the measurement. Section III details the signal extraction, detector response and systematic uncertainties involved in this measurement. The results and comparisons with other measurements and models are presented in Section IV. The final conclusions are presented in Section V.

#### II. EXPERIMENTAL APPARATUS AND DATA SET

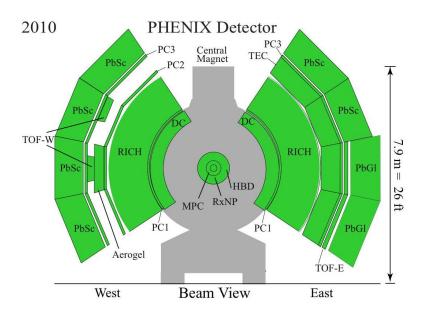

FIG. 2. (Color online) The PHENIX Central Arm Spectrometers for the 2010 data taking period.

The PHENIX experiment measures quarkonia at midrapidity through their dielectron decays with the two-arm central spectrometers [56] shown in Fig. 2. The central arm detectors measure electrons, photons, and hadrons over pseudorapidity of  $|\eta| < 0.35$  with each arm covering azimuthal angle  $\Delta \phi = \pi/2$ . Charged particle tracks in the central arms are reconstructed using the drift chambers (DC), the pad chambers, and the collision point. Electron candidates are selected using information from the ring-imaging Čerenkov detector (RICH) and the electromagnetic calorimeter (EMCal) [57]. The total radiation length before the DC during the 2006 p+p run was 0.4%. During the 2010 Au+Au run more material was introduced from the hadron blind detector (HBD) which added 2.4% radiation lengths to what the detector had in 2006. In the 2010 run, the magnetic field configuration was also modified to cancel the field in the HBD volume, decreasing the momentum resolution by about 25%.

Beam interactions were selected with a minimum bias (MB) trigger that requires at least one hit (two in Au+Au collisions) per beam crossing in each of the two beam-beam counters (BBC) placed at  $3.0 < |\eta| < 3.9$ . In the Au+Au data set, this was the only trigger used. A dedicated EMCal-RICH-Trigger (ERT) was used in coincidence with the

MB trigger during the 2006 p+p data acquisition. The ERT required a minimum energy in any  $2\times2$  group of EMCal towers, corresponding to  $\Delta\eta \times \Delta\phi \approx 0.02\times0.02$  rad., plus associated hits in the RICH. The minimum EMCal energy requirement was 400 MeV for the first half of the run and 600 MeV for the second half.

The collision point along the beam direction was determined with a resolution of 1.5 cm in p+p collisions and 0.5 cm in Au+Au collisions, by using the difference between the time signals measured between the two BBC detectors. The collision point was required to be within  $\pm 30$  cm of the nominal center of the detector in p+p collisions and  $\pm 20$  cm in Au+Au collisions. The 2006 data sample was taken from  $N_{pp} = 143$  billion minimum bias events, corresponding to an integrated luminosity of 6.2 pb<sup>-1</sup>. The 2010 data sample was obtained from  $N_{AuAu} = 5.41$  billion minimum bias events, corresponding to 0.9 nb<sup>-1</sup>.

In p+p collisions, electron candidates were identified by requiring at least one fired phototube within an annulus 3.4  $< R_{\rm ring}[cm] < 8.4$  centered in the projected track position on the RICH. The RICH is filled with a CO<sub>2</sub> radiator at 1 atm. Pions with momentum larger than 4.8 GeV/c can also produce Čerenkov light in the RICH. Electron candidates are also required to be associated with an energy cluster in the EMCal that falls within  $4\sigma_{\rm position}$  of the projected track position and within  $4\sigma_{\rm E/p}$  of the expected energy/momentum ratio for electrons, where  $\sigma$  represents one standard deviation in the position and energy+momentum resolution of the EMCal+DC determined using electrons from fully reconstructed Dalitz decays. Figure 3 shows the distribution of the parameter used to select electrons in the EMCal using electron candidates used in high-mass dielectrons with  $p_T > 5~{\rm GeV/}c$ , above the Čerenkov threshold. Hadron contamination appears as an enhancement of this distribution for negative values. The distribution, after subtracting the background mainly composed of hadrons, represents a clean sample of electrons for  $(E/p) - 1 < 4\sigma_{E/p}$ .

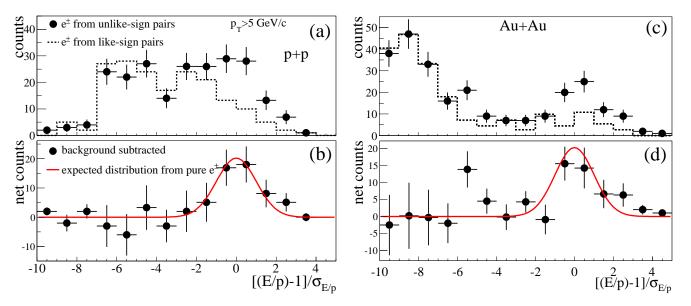

FIG. 3. (Color online) Distribution of the parameter used to identify electrons with the EMCal. E/p is the ratio between the energy deposited by the particle in the EMCal cluster and its momentum,  $\sigma_{E/p}$  is the variance of the expected energy/momentum expected for electrons. The sample shown in (a) from p+p collisions and (c) from Au+Au collisions is from unlike-sign electron pairs (containing signal+combinatorial background) and like-sign pairs (containing only background). (b) and (d) are the background subtracted distributions along with the expected line shape from pure electrons.

In the Au+Au analysis, the cuts were optimized by looking at the parameters in the detector simulations using generated  $\Upsilon \to e^+e^-$  decays embedded into real data for the signal, and the real data like-sign dielectrons as a background. As a result of the optimization, we require:

- ullet at least two fired phototubes within an annulus  $3.4 < R_{\rm ring} [{
  m cm}] < 8.4$  centered in the projected track position on the RICH
- $\chi^2/npe0 < 25$ , a variable defined as  $\chi^2$ -like shape of the RICH ring associated to the track over the number of photoelectrons detected in the ring
- the displacement between the ring centroid and the track projection should be smaller than 7cm
- EMCal cluster-track matching should be smaller than  $3\sigma_{\text{position}}$
- EMCal cluster energy/momentum ratio should be larger than  $-2.5\sigma_{\rm E/p}$ .

These tighter cuts allowed a better hadron rejection as can be seen in Figure 3-c compared to the p+p sample in Figure 3-a.

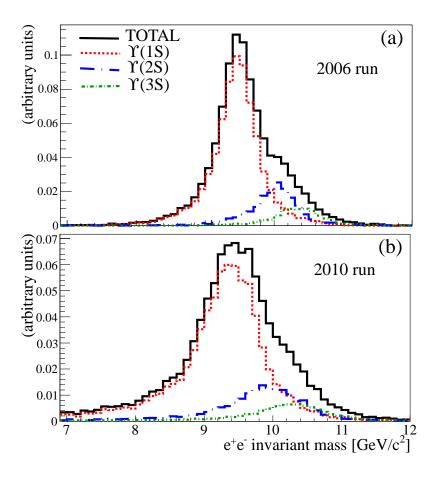

FIG. 4. (Color online) Invariant mass distribution of simulated  $\Upsilon$  (1S+2S+3S) using the PHENIX detector simulation and relative  $\Upsilon$  yields from CDF experiment [47] in 2006 run (a) and 2010 run (b) detector configurations.

Figure 4 shows the reconstructed invariant mass distribution for the three  $\Upsilon$  states from PHENIX detector simulations in the 2006 p+p run configuration and in 2010 Au+Au configuration. The detector is not able to separate the three states and a single peak should be observed. In the 2010 detector configuration the addition of more material in the detector introduced more bremsstrahlung for the electrons increasing the low mass tail of the peaks.

#### III. ANALYSIS PROCEDURE

#### A. Dielectrons from $\Upsilon$ in the Central Arms

279

281

282

283

284

285

287

The invariant mass was calculated for all electron pairs. Dielectron contributions to  $\Upsilon$  decays are clearly identified as a peak in the unlike-sign invariant mass distributions around the  $\Upsilon$  mass range  $8.5 < M_{\rm ee} [{\rm GeV}/c^2] < 11.5$  (Fig. 5). There were 12 unlike and one like-sign dielectron within this mass region from the p+p sample. In the Au+Au sample there were 22 unlike and 3 like-sign pairs in the same mass region.

Figure 6 shows the p+p dielectron mass spectrum over an extended mass region after the like-sign distribution (used to estimate combinatorial background) has been subtracted from the unlike-sign data. Figure 7 shows the same invariant mass spectrum in the  $\Upsilon$  mass region for p+p and Au+Au data. The line shape of the  $\Upsilon$  mass peak determined from simulations (Fig. 4) cannot be validated by the real data given the low statistics in both p+p and Au+Au samples. In addition, the relative contributions from different  $\Upsilon$  states are unknown in Au+Au data. The number of  $\Upsilon$  counts was determined from a direct count of unlike-sign and like-sign dielectrons in the  $\Upsilon$  mass region and the fraction of correlated background  $f_{\rm cont}$  in the same mass range. Given the low counts for the signal and background, Poisson statistics precludes the use of a simple subtraction. Therefore, the  $\Upsilon$  signal is determined from

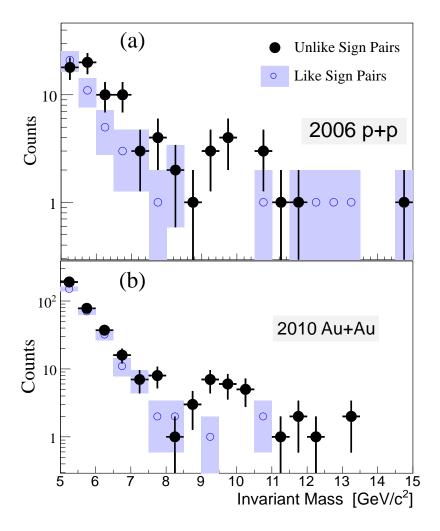

FIG. 5. (Color online) Invariant mass distribution of unlike-sign and like-sign dielectrons in the  $\Upsilon$  mass region taken from p+p (a), and Au+Au collisions (b).

$$N_{\Upsilon} = \langle s \rangle_P (1 - f_{\text{cont}}), \tag{1}$$

where  $\langle s \rangle_P$  is the average signal from a joint Poisson distribution from the foreground unlike-sign f and background like-sign b dielectron counts in the  $\Upsilon$  mass region [57]

$$P(s) = \sum_{k=0}^{f} \frac{(b+f-k)!}{b!(f-k)!} \frac{1}{2} \left(\frac{1}{2}\right)^{b+f-k} \frac{s^k e^{-s}}{k!}, \tag{2}$$

294 and the statistical uncertainty corresponds to one standard deviation of the P(s) distribution.

295

#### B. Estimation of the continuum contribution

The correlated background underneath the  $\Upsilon$  region is determined from fits of the expected mass dependence of Drell-Yan, correlated electrons from B meson decays and possible contamination of hadrons within jets.

The Drell-Yan contribution was estimated from next-to-leading order (NLO) QCD calculations [58]. These calculations are known to reproduce lower and higher energy data at Fermilab [59, 60]. The calculated cross section was used to generate dielectrons propagated through the GEANT [61] based detector simulation. The Drell-Yan contribution is

modified by isospin and initial state effects in Au+Au collisions. After calculating the Drell-Yan cross section for p+n and n+n collisions, we found that the Au+Au cross section per binary collision is  $f_{\rm iso}=89\%$  of that of p+p collisions because of the isospin effect. The initial state effects were accounted for by using a parton modification factor from the EPS09 parametrization,  $R_q^{DY}\left(Q^2,x_1,x_2\right)$ , for both Au nuclei. The expected Drell-Yan yield in Au+Au collisions  $\left(Y_{DY}^{\rm AuAu}\right)$  relative to the yield in p+p collisions  $\left(Y_{DY}^{pp}\right)$  is:

$$\frac{Y_{\mathrm{DY}}^{\mathrm{AuAu}}\left(M_{\mathrm{ee}}\right)}{N_{\mathrm{coll}}} = Y_{\mathrm{DY}}^{pp}\left(M_{\mathrm{ee}}\right) \cdot f_{\mathrm{iso}} \cdot R_{q}^{DY}\left(Q^{2}, x_{1}, x_{2}\right),\tag{3}$$

where  $N_{\text{coll}}$  is the number of binary collisions.  $Q^2$ ,  $x_1$  and  $x_2$  are taken event-by-event from a PYTHIA simulation [62]. Theoretical uncertainties from the NLO calculation, EPS09 quark modification factor  $\left(R_q^{DY}\left(Q^2,x_1,x_2\right)\right)$  and overall detector response were accounted for in the Drell-Yan contribution.

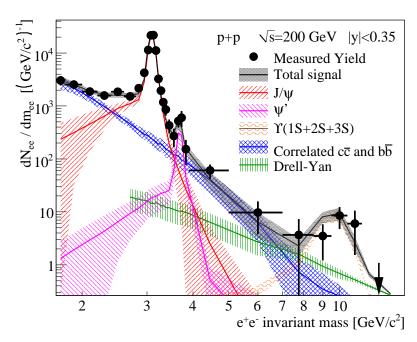

FIG. 6. (Color online) Fitted components to the correlated dielectron mass spectrum in the p+p sample. The bands correspond to the uncertainties obtained from the fit, changes in the heavy flavor generator and theoretical uncertainties in the Drell-Yan contribution.

The line shape of the correlated high-mass dielectron distribution from heavy flavor decays in p+p collisions was studied in detail in [57]. Two approaches were used: (1) a dielectron generator using the measured  $p_T$  distribution of single electrons from heavy flavor with a random opening angle and (2) a heavy flavor simulation from PYTHIA in the hard scattering mode to emulate NLO contributions. Both generated dielectron distributions were introduced into the detector simulation and reconstructed like the real data. The mass distribution from heavy flavor decays was normalized according to a fit to the dielectron spectrum starting at an invariant mass at 1.7 GeV/ $c^2$ , thus including the  $J/\psi$  and the  $\psi'$  peaks. Figure 6 shows the overall dielectron fit extended to the  $\Upsilon$  region. The uncertainty bands represent the quadratic sum of the fit uncertainties and the differences between the approaches (1) and (2). The Drell-Yan band represents the quadratic sum of theoretical uncertainties and detector response uncertainties. The extrapolation of the heavy flavor contribution to the  $\Upsilon$  mass range 8.5 <  $M_{\rm ee}[{\rm GeV}/c^2]$  < 11.5 in p+p data yields 0.29  $\pm$  0.12 counts, which corresponds to 3.9  $\pm$  1.7 pb. The PYTHIA simulation, including parton shower terms, yields an estimate that the correlated bottom contribution in this mass range is 3.2 pb, in agreement with the fit extrapolated result.

Jets can contribute to the correlated background in two ways: Dalitz decays from  $\pi^0$  pairs within the jet and correlated hadron pair contamination. For a  $\pi^0$  pair to produce a correlated electron pair in the  $\Upsilon$  mass region, each of the  $\pi^0$ s should have a transverse momentum larger than the mass of the  $\Upsilon$ , which is a possibility ruled out by the current statistics. Figure 3 shows a not significant hadron contamination in the high-mass dielectrons in p+p data after combinatorial background subtraction. Hadron contamination was found to be negligible within uncertainties. Contributions from electron-hadron correlations are also assumed to be negligible.

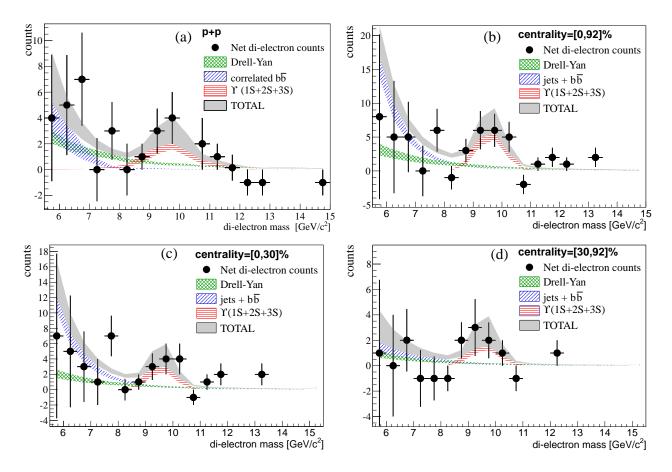

FIG. 7. (Color online) Fits to the correlated dielectron mass distribution around the  $\Upsilon$  region obtained in p+p collisions (a) and Au+Au collisions in three centrality bins (b,c,d). The bands correspond to fitting and theoretical uncertainties for the Drell-Yan estimation. Fitting results are used only for correlated background estimations.

The resulting continuum fraction in the selected mass range is  $f_{\rm cont}^{pp}=13\pm4\%$  in the p+p sample. The continuum fraction was also determined with a maximum likelihood fit using the combinatorial background, Drell-Yan, B meson and  $\Upsilon$  line shapes with free parameters for their scales, except the combinatorial background which has a fixed scale. The total continuum found in this manner was consistent with that estimated with a fixed Drell-Yan scale. The fit (without any hadron contribution) provides a good description of the mass distribution.

329

330

331

332

We cannot calculate the continuum contributions in Au+Au collisions in the same way as we do for p+p collisions given the unknown nuclear modification of bottom quarks. Contributions from correlated hadrons may also start to be significant in a high-occupancy environment. We thus perform a fit to separate the continuum background from the  $\Upsilon$  signal. The dielectron spectrum is described by the following function:

$$f(m) = N_{\text{like}} Y_{\text{like}}(m) + Y_{\text{DY}}(m)$$

$$+ N_{\text{b\bar{b},jet}} Y_{\text{b\bar{b},jet}}(m) + Y_{\Upsilon}(m)$$

$$N_{\text{like}} = \frac{2\sqrt{N_{\text{e}^{+}\text{e}^{+}} N_{\text{e}^{-}\text{e}^{-}}}}{\int Y_{\text{like}}(m) dm}$$

$$N_{\text{b\bar{b},jet}} = \left[ N_{\text{cont}} - \int_{m_{\text{low}}}^{m_{\text{high}}} Y_{\text{DY}}(m) dm \right]$$

$$Y_{\Upsilon}(m) = \frac{N_{\text{g}}}{\sqrt{2\pi}\sigma_{\text{g}}} \exp \left[ -\frac{1}{2} \left( \frac{m - 9.5}{\sigma_{\text{g}}} \right)^{2} \right]$$

$$(4)$$

where  $N_{\rm like} \sim 1$  is the normalization of the like-sign distribution [36],  $N_{\rm e^+e^+} + N_{\rm e^-e^-} = 2613$  is the number of like-sign dielectron pairs over the mass range  $5 < M_{\rm ee} [GeV/c^2] < 15$ ,  $Y_{\rm like}(m)$  is the like-sign dielectron mass distribution

from real data which account for the combinatorial background and a fraction of the correlated background,  $Y_{\rm DY}(m)$  is the Drell-Yan contribution as calculated in Eq. (3),  $m_{\rm low}=8.5~{\rm GeV}/c^2$  and  $m_{\rm high}=11.5~{\rm GeV}/c^2$  define the mass range used in the continuum normalization,  $N_{\rm cont}$  is the continuum contribution in the  $\Upsilon$  mass region,  $Y_{\Upsilon}(m)$  is a Gaussian function accounting for the  $\Upsilon$  peak where  $\sigma_{\rm g}$  is the effective peak width of all three  $\Upsilon$  states combined, and  $Y_{\rm b\bar{b}, jet}(m)$  is a function normalized in the  $\Upsilon$  mass range which accounts for the correlated open bottom and hadrons from jets. We assumed both a power law and an exponential function for the correlated bottom and jet contributions:

$$Y_{\rm b\bar{b}, jet}(m) = \begin{cases} (\alpha + 1)m^{\alpha} / \left(m_{\rm high}^{\alpha - 1} - m_{\rm low}^{\alpha - 1}\right) \\ \alpha e^{\alpha m} / \left(e^{\alpha \cdot m_{\rm high}} - e^{\alpha \cdot m_{\rm low}}\right) \end{cases}$$

The parameters  $N_{\rm cont}$ ,  $\alpha$ ,  $N_{\rm g}$  and  $\sigma_{\rm g}$  were fit to the unlike-sign dielectron spectrum between 5 and 16 GeV/ $c^2$  using a maximum likelihood method. Figure 7 shows the  $f(m)-N_{\rm like}Y_{\rm like}(m)$  fitting result assuming a power law function for the bottom-jet contribution. The bands represent the fit and theoretical uncertainties. The continuum estimate changes by up to 0.9% depending on the choice of the bottom+jet contribution function  $(Y_{\rm b\bar{b},jet}(m))$ . Table III lists the number of net counts and the continuum fraction for p+p and three centrality ranges in the Au+Au data. The fraction of continuum in Au+Au data obtained from these fits was found to be larger than in p+p data. This may reflect that the nuclear modification of Drell-Yan in Au+Au is small compared to the  $\Upsilon$  yield modification.

## C. Mass cut efficiency

The  $\Upsilon$  count is all made in the mass range  $8.5 < M_{\rm ee} [{\rm GeV}/c^2] < 11.5$ . The reconstructed  $\Upsilon$  family peaks may have some contribution at masses out of this range. According to the detector simulation using the CDF results [50] for the relative yields, the mass range  $8.5 < M_{\rm ee} [{\rm GeV}/c^2] < 11.5$  contains a fraction  $\varepsilon_{\rm mass} = 0.94 \pm 0.05$  of the  $\Upsilon(1S + 2S + 3S)$  yield in the 2006 p+p data set. The uncertainty of this estimate comes from the mass fit to the p+p data and from the difference between real data and simulations. In the Au+Au analysis, the evaluation of the detector occupancy effect on the efficiency included the mass cut used in the analysis. Variations in the detector mass resolution during this study indicate a systematic uncertainty in the mass cut efficiency of 6% in Au+Au data. The number of  $\Upsilon$  counts has a 2% variation when the normalization of the like-sign dielectrons ( $N_{\rm like}$ ) is taken from different mass ranges. This is assigned as a systematic uncertainty on the yield.

# D. Detector Response

362

367

370

371

372

375

377 378 The GEANT based detector simulation was tuned as described in [57]. The acceptance and efficiency in this analysis was obtained from  $\Upsilon(1S+2S+3S)$  dielectron decays generated by PYTHIA, requiring that they fall into a rapidity range of |y| < 0.5. The relative yield between  $\Upsilon$  states were taken to be those reported by CDF [50]. This same detector simulation was used to estimate the detector response for the heavy flavor and Drell-Yan background line shapes as described in the previous section.

In the p+p sample, the overall acceptance and efficiency  $Acc \times \varepsilon$  for  $\Upsilon$ s calculated from simulations was found to be  $(2.33 \pm 0.23)$  % in the |y| < 0.5 rapidity region. The uncertainty of this estimate is from variations in the detector performance during the run, mismatches between the detector simulation and the detector activity in real data and variations of the  $p_T$  shape introduced in simulation (Fig. 8-a).

The BBC trigger samples a cross section of  $\sigma_{\rm pp} \times \varepsilon_{\rm BBC} = 23 \pm 2.2$  mb in p+p collisions, according to Vernier scans [64]. However, it samples a larger fraction of the cross section when the collision includes a hard scattering process. Studies with high  $p_T$   $\pi^0$  yields showed an increase of the luminosity scanned by the BBC by a factor of  $1/\varepsilon_{\rm BBC^{hard}}$ ,  $\varepsilon_{\rm BBC}^{hard} = (0.79 \pm 0.02)$  [65]. In Au+Au data the BBC scans  $92 \pm 3\%$  of the total Au+Au inelastic cross section and there is no bias from hard scattering ( $\varepsilon_{\rm BBC}^{hard} = 1$ ). The EMCal-RICH trigger (ERT) efficiency of dielectrons was found to be  $(79.6 \pm 3.6)\%$  in the p+p sample when emulating the ERT in MB data. The ERT was not used for the Au+Au data.

In the Au+Au data, the electron identification cuts were tighter, resulting in a calculated acceptance and efficiency  $Acc \times \varepsilon = 1.41 \pm 0.05\%$  (point at 85% centrality in Fig. 9-b). To quantify additional inefficiencies from the detector occupancy, the raw detector signal from simulated  $\Upsilon$  dielectron decays was embedded in real raw data. The simulated  $\Upsilon$  was generated at the same collision point measured in the real event. The reconstruction, fitting and mass cuts of the embedded data were the same as those used in real data analysis. The  $p_T$  and collision centrality dependence of the resulting fraction of  $\Upsilon$  counts in the reconstructed embedded data are shown in Fig. 9. The big difference between

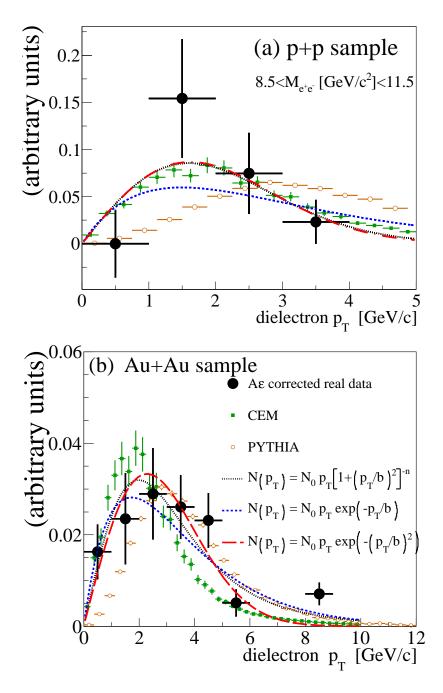

FIG. 8. (Color online) Transverse momentum dependence of acceptance corrected dielectron net counts in the  $\Upsilon$  mass region from p+p (a) and centrality integrated Au+Au (b) collisions. The lines are functions and  $\Upsilon$  yield estimations (Color Evaporation Model-CEM [63] and PYTHIA [62]) fitted to the distributions.

the detector efficiency obtained in p+p data and peripheral Au+Au reflects the tight cuts needed in Au+Au because of the larger occupancy and additional material in front of the detector in 2010 run.

387

389

Because we do not have the statistic precision to determine the transverse momentum distribution of the  $\Upsilon$ , we must employ models for the  $p_T$  dependence to determine an overall acceptance and efficiency. Five functions were used for the  $p_T$  distribution: a shape from generated  $\Upsilon$  decays in PYTHIA, a prediction from the color evaporation model [63] and three fitted functions  $f(p_T)$  to the acceptance corrected real data distribution (Fig. 8). The  $p_T$  integrated acceptance and efficiency is determined by an average using the  $p_T$  dependence shown in Fig. 9 and these functions as weights. The difference between these calculations and the default weighing using PYTHIA as an input is within 7.8% in p+p and 7.9% in Au+Au samples.

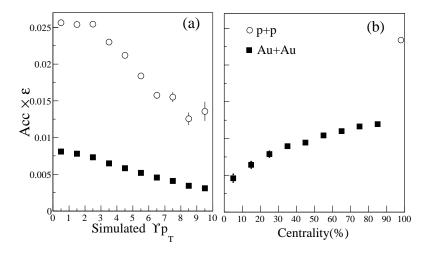

FIG. 9. Dependence of the acceptance  $\times$  efficiency for detected  $\Upsilon$  dielectron decays in p+p and Au+Au collisions on (a) transverse momentum in 0%–92% centrality and (b) collision centrality. The bars represent statistical uncertainties in the simulation.

TABLE III. Summary of values used in BdN/dy (5) and  $R_{AA}$  (7) calculations.

The final values for the efficiency in our wide centrality bins are also sensitive to the true centrality dependence of the  $\Upsilon$  production. To estimate this systematic uncertainty we assume two different centrality dependence models:

(1) binary collision scaling and (2) participant collision scaling. Within our centrality ranges, we find that these two models yield less than a 7% difference and we include this in our occupancy systematic uncertainty.

IV. RESULTS

The  $\Upsilon \to e^+e^-$  invariant multiplicity at midrapidity, BdN/dy, is calculated by

$$B\frac{dN}{dy} = \frac{1}{\Delta y} \frac{N_{\Upsilon}}{(N_{\rm BBC}/c) \cdot Acc \cdot \varepsilon} \tag{5}$$

where B is the dielectron branching ratio,  $N_{\Upsilon}$  is the number of  $\Upsilon$  candidates in the data set as defined in (1),  $\Delta y = 1$  corresponds to the rapidity range used in simulation (±0.5),  $N_{\rm BBC}$  is the number of analyzed events,  $c = \varepsilon_{\rm BBC}/\varepsilon_{\rm BBC}^{\rm hard}$  is a correction factor accounting for the limited BBC efficiency and the trigger bias present in events which contain a hard scattering in p+p collisions as explained in Section III D, Acc is the  $\Upsilon$  acceptance and  $\epsilon$  is the  $\Upsilon$  reconstruction efficiency which includes the ERT efficiency. Table III summarizes the numbers used to calculate the  $\Upsilon$  yields using Eq. 5. Table IV details the systematic uncertainties involved in the yield calculation. The resulting invariant multiplicities are reported in Table V.

The  $\Upsilon(1S+2S+3S)$  cross section in p+p collisions is

398

$$B\frac{d\sigma_{\Upsilon}}{dy}\Big|_{|\mathbf{y}|<0.5} = B\frac{dN}{dy} \times \sigma_{\mathrm{pp}} \tag{6}$$

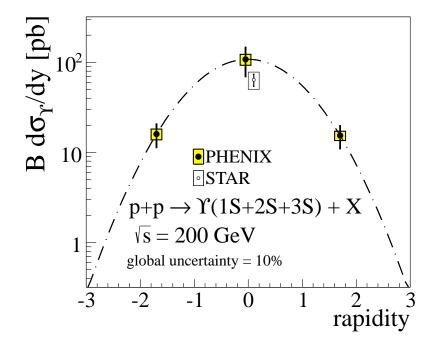

FIG. 10. (Color online) Rapidity dependence of  $\Upsilon(1S+2S+3S)$  yield measured by PHENIX, forward rapidity result from [53] and STAR midrapidity from [54]. Dashed line is a Gaussian function fitted to the points. The points at zero rapidity are shifted for clarity.

$$= 108 \pm 38(\text{stat}) \pm 15(\text{syst}) \pm 11(\text{lum}) \text{ pb},$$

where  $\sigma_{\rm pp} = 42 \,\mathrm{mb}$  is the p+p inelastic cross section at  $\sqrt{s} = 200 \,\mathrm{GeV}$ .

Figure 10 shows the rapidity dependence of  $\Upsilon$  measured in p+p collisions by PHENIX in the mid- (this analysis), forward rapidities [53] and the STAR result at midrapidity [54]. Figure 11 presents the collision energy dependence of the differential cross section at midrapidity along with a NLO calculation using the color evaporation model for the bottomonium hadronization [63].

In addition to the Au+Au 0%–92% centrality sample, we present data in two centrality bins, 0%–30% most central and 30%–92% most central. Using a Monte Carlo simulation based on the Glauber model in [74], we estimated  $N_{\text{coll}}$ , the average number of binary nucleon-nucleon collisions and  $N_{\text{part}}$ , the average number of participants, for all data samples. Figure 12 shows the  $N_{\text{coll}}$  normalized invariant yield of  $\Upsilon$  decays as a function of the number of participants. For central Au+Au collisions, we observe a reduction of the yield relative to a pure  $N_{\text{coll}}$  scaling that is typical of hard scattering processes.

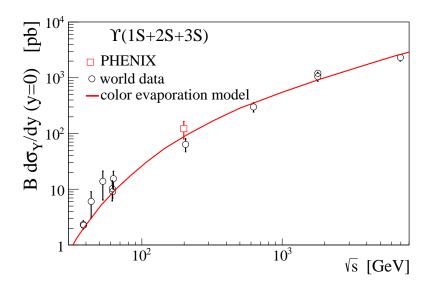

FIG. 11. (Color online) Energy dependence of the  $\Upsilon(1S+2S+3S)$  differential cross section at midrapidity in p+p and  $p+\bar{p}$  collisions [49, 52, 54, 66–73]. The curve is the estimation using the color evaporation model [63].

TABLE V. Summary of the measured  $\Upsilon$  invariant multiplicities, BdN/dy, for one p+p three Au+Au data sets.

Centrality	BdN/dy
$p+p \left(\times 10^9\right)$	$2.7 \pm 0.9 \text{ (stat)} \pm 0.4 \text{ (syst)}$
$0\%-92\% \ (\times 10^7)$	$4.1^{+1.1}_{-1.2} \text{ (stat)} \pm 0.9 \text{ (syst)}$
$0\% - 30\% (\times 10^{7})$	$8.7^{+2.9}_{-3.1}~(\mathrm{stat})\pm1.8~(\mathrm{syst})$
$30\%-92\% \left(\times 10^{7}\right)$	$1.6^{+0.8}_{-0.9}~(\mathrm{stat})\pm0.3~(\mathrm{syst})$

The nuclear modification factors for the binned and integrated 0%–92% centrality data set  $(R_{AA})$  were calculated as:

$$R_{AA} = \frac{dN/dy_{\text{AuAu}}}{\langle N_{\text{coll}} \rangle dN/dy_{\text{pp}}} \tag{7}$$

and are reported in Table VI. A global uncertainty of 40% is obtained from the quadratic sum of the relative uncertainty from 38% p+p data (statistical+systematic) and 12% from the Glauber estimate of the number of collisions. We assume none of the systematic uncertainties are correlated between p+p and Au+Au samples given the different collision environment and changes in the detector configuration between 2006 and 2010 runs, namely active area differences and the installation of the hadron blind detector in 2010 which increased the radiation length from 0.4% to 2.8%.

If the  $\Upsilon(1S+2S+3S)$  yield for Au+Au collisions is equal to the yield for p+p collisions times the number of binary collisions in Au+Au collisions, then  $R_{AA}=1$  and there are no nuclear modification effects. Figure 13 shows the  $R_{AA}$  as a function of the number of participants for the two centrality-split classes. The inclusive  $\Upsilon$  states are suppressed in central 200 GeV Au+Au collisions, corresponding to large  $N_{\rm part}$ . However, the degree of suppression in semi-peripheral collisions is unclear, due to limited statistics.

TABLE VI. Summary of the measured  $\Upsilon$  nuclear modification factors,  $R_{AA}$ , for Au+Au data sets.

Centrality	$R_{AA}$
0%-92%	$0.58 \pm 0.17 (\mathrm{stat}) \pm 0.13 (\mathrm{syst}) \pm 0.23 (\mathrm{global})$
0%-30%	$0.50 \pm 0.18 \text{ (stat)} \pm 0.11 \text{ (syst)} \pm 0.20 \text{ (global)}$
30%-92%	$0.84^{+0.45}_{-0.48} \text{ (stat)} \pm 0.18 \text{ (syst)} \pm 0.34 \text{ (global)}$

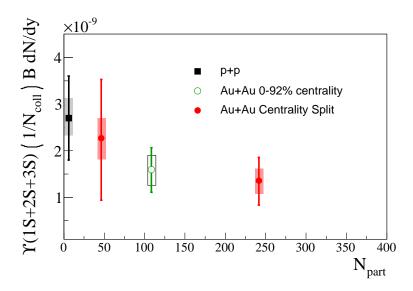

FIG. 12. (Color online) The  $N_{coll}$  normalized invariant yield of  $\Upsilon$ s produced during the 2006 p+p and the 2010 Au+Au operations, as a function of  $N_{part}$ ..

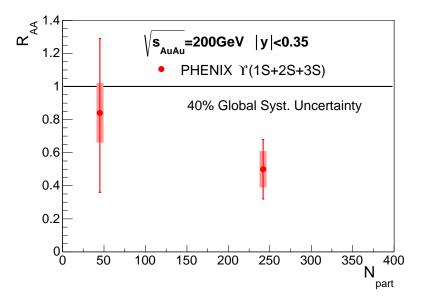

FIG. 13. (Color online) Nuclear modification factor for centrality binned data plotted as a function of N<sub>part</sub>.

In most central events, the suppression is comparable to what is observed in p(d)+A collisions [46, 51–53]. Based on the lattice calculations discussed before, the bottomonia excited states should be completely dissociated in the core of Au+Au collisions at RHIC. Table VII summarizes what would be the  $R_{AA}$  observed in this study in case the only nuclear matter effect observed is the complete suppression of these excited states. The estimation is based on the composition of the  $\Upsilon$  states measured and the decays to the  $\Upsilon(1S)$  reported in Tables I and II. The  $R_{AA}$  obtained in this analysis is consistent with the suppression of excited states if other initial and final state effects are ignored. The result presented in this work agrees with the STAR experiment at the same energy [54]. The CMS ex-

The result presented in this work agrees with the STAR experiment at the same energy [54]. The CMS experiment reported centrality dependent nuclear modification factors for the separated  $\Upsilon(1S)$  and  $\Upsilon(2S)$  states at  $\sqrt{s_{NN}}$ =2.76 TeV in Pb+Pb collisions at the LHC [75]. CMS also reported an upper limit of  $R_{AA}(\Upsilon(3S))$  of 0.10 at the 95% confidence level. Figure 14 compares the observed inclusive  $\Upsilon(1S+2S+3S)$  nuclear modification factor observed by PHENIX with STAR and the inclusive  $\Upsilon(1S+2S)$  measurement by CMS at higher energy showing that the observed nuclear modification factors are very similar at the two quite different energies.

439

Additionally, it is important to compare the measurements to various model predictions. A model by R. Rapp *et al.* has frequently been used to interpret  $J/\psi$  production [76]. It uses a rate-equation approach, which accounts for both

TABLE VII.  $\Upsilon(1S+2S+3S)$   $R_{AA}$  expected when the excited states are completed suppressed in Au+Au collisions along with the measured result in the 30% most central collision regime. Estimations based on Tables I and II.

suppression from cold nuclear matter, color screening of excited states (seen in Fig. 1) and regeneration mechanisms in the QGP and hadronization phases of the evolving medium. This study looked at two scenarios. The first is the strong binding scenario where the bottomonium binding energy was not affected by the presence of the QGP, remaining at the values found in vacuum, and is shown in Fig. 15. The other is the weak binding scenario where the bottomonium bound-state energies are significantly reduced in the QGP, relative to the vacuum state, adopting the screened Cornell-potential results of [77] and is shown in Fig. 16. Our data, albeit with large statistical uncertainties, are consistent with both versions of this model.

More recently, two new models were suggested by Strickland and Bazow [78] based on the potential model [77], with the addition of an anisotropic momentum term. Models A and B are identical, except for an additional term in Model B which adds an entropy contribution to the free energy. Figure 17 shows the PHENIX measurement along with the two model predictions, each with a variety of values for the ratio of the shear viscosity to the entropy density. No definitive statement can be made regarding the shear viscosity. However, the extreme potential B case appears to be favored.

### V. CONCLUSIONS

In summary, we have studied the production of the sum of  $\Upsilon$  states 1S, 2S and 3S at  $\sqrt{s_{NN}}=200$  GeV in the midrapidity region. The dielectron channel differential cross section in p+p collisions is  $Bd\sigma/dy=108\pm38$  (stat)  $\pm 15$  (syst)  $\pm 11$  (luminosity) pb. The nuclear modification seen in Au+Au minimum bias collisions is  $0.58\pm0.17$  (stat)  $\pm 0.13$ (syst)  $\pm 0.23$  (global), whereas it is  $0.84^{+0.45}_{-0.48}$  (stat)  $\pm 0.18$  (syst)  $\pm 0.34$ (global) in the mid-peripheral events and  $0.50\pm0.18$  (stat)  $\pm 0.11$  (syst)  $\pm 0.20$ (global) in the 30% most central events. The nuclear modification is consistent with the complete suppression of the bottomonium excited states ( $\Upsilon(2S)$ ,  $\Upsilon(3S)$  and  $\chi_B$ ), in qualitative agreement with most calculations as compiled in Fig. 1, assuming no cold nuclear matter effects. There are several detailed model calculations that show good agreement with our measured modifications. The nuclear modification factors measured by PHENIX are similar to measurements by STAR at the same energy and by CMS at much higher
