(Dated: February 29, 2016)

Total thermal radiative neutron cross sections have been measured on natural and enriched isotopic targets containing ^{6,7}Li, ⁹Be, ^{10,11}B, ^{12,13}C, and ^{14,15}N with neutron beams from the Budapest Reactor. Complete neutron capture γ -ray decay schemes were measured for each isotope. Absolute transition probabilities have been determined by a least-squares fit of the transition intensities, corrected for internal conversion, to the (n,γ) decay schemes. The γ -ray cross sections were standardized using stoichiometric compounds containing both the isotope of interest and another element whose γ -ray cross sections are well known. Total cross sections, σ_0 , were then determined for each isotope from the γ -ray cross sections and transition probabilities. For the ¹¹B (n,γ) ¹²B reaction decay transition probabilities were determined for the γ -rays from ¹²B ($t_{1/2}$ =20.20 ms) β ⁻-decay.

I. INTRODUCTION

Precise thermal neutron capture γ -ray cross sections have been measured for all naturally abundant elements except He and Pm at the Budapest Reactor [1, 2]. These data were evaluated, together with additional information from the literature, to generate the Evaluated Gamma-ray Activation File (EGAF) [3] and were published in the Handbook of Prompt Gamma Activation Analysis [4]. The (n,γ) data can be used to determine total radiative thermal neutron capture cross sections, σ_0 , if the level scheme is complete as is the case for the light isotopes.

The elements H, Li, Be, and B are important strategic materials identified by the US Department of Defense [5] while the elements C, N, and O are abundant in nature and important for dosimetry, neutron transport calculations and shielding determinations. Previously we have published the total radiative thermal neutron capture cross sections for ²H and ^{16,17,18}O [6] and in this work we discuss our measurements of the ^{6,7}Li, ⁹Be, ^{10,11}B, ^{12,13}C, and ^{14,15}N cross sections.

II. EXPERIMENT

The ^{6,7}Li, ⁹Be, ^{10,11}B, ^{13,14}C, and ^{14,15}N(n, γ) neutron capture γ -ray spectra were measured in both guided thermal and cold neutron beams at the 10-MW Budapest Reactor [1]. Neutrons entered the evacuated target holder and continued to the beam stop at the rear wall of the guide hall. The target station, where both primary and secondary γ -rays can be measured in low background conditions, is located ≈ 30 m from the reactor. The neutron flux at the target ranged from 2.3×10^8 cm⁻²s⁻¹ for cold beams to 5×10^7 cm⁻²s⁻¹ for thermal beams during these experiments.

Prompt γ -rays from the target were measured with an n-type high-purity, 27% efficient, germanium (HPGe) detector with closed-end coaxial geometry located 23.5 cm from the target. The detector is Compton-suppressed by a BGO-scintillator guard detector annulus and surrounded by 10-cm thick lead shielding. Counting efficiency was calibrated from 50 keV to 10 MeV with radioactive sources and (n,γ) reaction γ -rays to an accuracy of better than 1% from 0.5-6 MeV and better than 3% at other energies [7]. The γ -ray spectra were analyzed with the Hypermet-PC program [7, 8].

III. NEUTRON SEPARATION ENERGIES

The γ -ray energy calibrations were also performed using the efficiency calibration sources. Level energies, including the neutron separation energy, were calculated by a least-squares fit of the γ -rays to the level scheme with the computer code GAMUT [9]. The χ^2/f quality of each fit of the γ -rays to the level scheme is reported in the decays scheme figure captions. Our measured neutron separation energies are compared to the recent compilation of Wang *et al* [10].

IV. CROSS SECTION ANALYSIS

Natural and isotopically enriched targets were suspended in teflon holders to reduce the target background and irradiated in the neutron beam to obtain high statistics γ -ray spectra. The small contribution from internal conversion for these low-Z isotopes was dominated by internal pair conversion (IPC), which can exceed 0.3% for high energy transitions, and was calculated using the

FIG. 1: Decay scheme for ¹⁴N(n, γ). Total transition probabilities, $P_{\gamma+e}$, are shown. The fit of the γ -rays to the level scheme gives $\chi^2/f=1.3$.

BRICC code [14] assuming multipolarities taken from the Evaluated Nuclear Structure Data File (ENSDF) [15]. This correction had been ignored in earlier work but became more significant in our high precision measurements.

Complete neutron capture decay schemes were constructed for each of the isotopes discussed here. The absolute γ -ray transition probabilities were then determined by a least-squares fit of the transition intensities to the decay scheme where we assume that the intensity is balanced feeding/deexciting each intermediary level and the total primary transition intensity deexciting the capture state (CS) equals the secondary intensity populating the ground state (GS). The fitted transition probabilities provide a well balanced, energy conserving decay scheme.

The γ -ray cross sections were standardized using stoichiometric high purity targets containing the isotope of interest and a comparator isotope that emits γ -rays with well known cross sections. Each target was analyzed by PGAA to search for γ -rays from target impurities and no significant impurities were found for the targets used in these experiments. The primary comparator for this work is the 2223-keV transition produced by the ¹H(n, γ) reaction where σ_{γ} =332.5±0.7 mb [6, 16]. The secondary standards ¹²C and ¹⁴N were calibrated with respect to hydrogen as discussed below. The total radiative thermal neutron cross sections are calculated as shown in Eq. 1 where Abd(%) is percent abundance of the isotope of interest in the target. This method eliminates

$$\sigma_0 = \frac{\sigma_\gamma}{P_\gamma(\%)Abd(\%)} \times 10^4 \tag{1}$$

the need to know the absolute neutron flux or the neutron spectrum for these non-1/v isotopes. For natural targets we use the standard abundances of Berglund and Wieser [17] and for enriched targets we use the abundances reported for the material.

Uncertainties in the cross section measurements are derived from the statistical uncertainties in the peak analysis of the γ -ray spectrum, determined by Hypermet, added in quadrature with the systematic uncertainties in

the isotopic abundance and standardization γ -ray cross sections. Each cross section discussed here is the result of several measurements and the goodness of fit for each weighted average value is determined by a chi^2/f test where f is he number if degrees of freedom.

A. ¹⁴N cross section

A 98% enriched deuterated urea (CD₄N₂O) target was irradiated for 233,034 seconds at the Budapest Reactor. 80 γ -rays, including 38 γ -rays observed in other experiments [12, 13] but too weak to be seen here, were placed in the ¹⁵N level scheme and are listed in Table I. The transition probabilities were fit to the capture γ -ray decay scheme, as discussed above, with a $\chi^2/f=0.42$. The ¹⁵N capture γ -ray decay scheme is shown in Fig. 1 where the level energies are calculated by a least squares fit to the γ -ray energies. The neutron separation energy, determined in this work, is $S_n=10833.22\pm0.05$ keV in agreement with the recommended value $S_n=10833.2951\pm0.0008$ keV [10].

The 1884.85 keV γ -ray cross section from ¹⁴N(n, γ) was standardized with respect to hydrogen using a variety of stoichiometric compounds summarized in Table II yielding a weighted average cross section from the seven measurements of 14.57 \pm 0.04 mb. The uncertainty includes

TABLE II: Calibration of the 1884.85 keV γ -ray cross section. The ¹⁴N natural abundance of 99.632 \pm 0.007% [17] was used for calculating the isotopic cross section. The weighted average includes an 0.02 mb statistical uncertainty with $\chi^2/f=1.6$ and a calibration uncertainty of 0.03 mb.

Weigh	nted Average	$14.57 {\pm} 0.04$

a statistical error of 0.02 mb and a calibration error of 0.03 mb. The same calibration cross section was used by Belgya [11] to calibrate the γ -ray cross sections of 14 strong transitions in ¹⁵N ranging from 1.7-8.3 MeV shown in Table I. Another accurate set of ¹⁴N(n γ) cross sections are available from Jurney *et al.* [13] but we chose the Belgya data because it corrects for an earlier systematic uncertainty in the high energy efficiency calibration. We also measured the cross section of the 10829.10 keV CS \rightarrow GS γ -ray as 10.7 \pm 0.4 mb. The total radiative cross

sections derived from all 15 measurements are consistent and led to a weighted average value of $\sigma_0(^{14}N)=80.0\pm0.4$ mb with a statistical uncertainty of 0.02 mb and a calibration uncertainty of 0.03 mb. This result is consistent with the previous measurements that are summarized in Table III.

FIG. 2: Decay scheme for ${}^{15}N(n,\gamma)$. The levels at 120.42and 397.27-keV were not populated in this reaction. Total transition probabilities, $P_{\gamma+e}$, are shown.

TABLE IV: ¹⁵N(n, γ) γ -ray energies, transition probabilities, and total cross sections measured on a pyridine target enriched to 98% in ¹⁵N. Two independent measurements were made of the 6129 keV γ -ray from ¹⁶N β^- decay. The uncertainty in the weighted average is nearly entirely statistical with $\chi^2/f=0.03$.

B. ¹⁵N cross section

The ¹⁵N(n, γ) thermal neutron radiative neutron capture decay scheme was not previously measured. To determine this cross section we irradiated a 98% ¹⁵N enriched pyridine (C₅H₅N) target with cold neutrons. We identified three γ -rays that are assigned to this reaction and listed in Table IV. The 2192-keV γ -ray is placed as a primary transition deexciting the CS to the 298.22-keV level [24] which decays by the 298-keV γ -ray to the GS. Both transitions have approximately equal intensities so this appears to be a simple γ -ray cascade as shown in Fig. 2. The third transition is the well known 6129-keV γ -ray from ¹⁶N β^- decay.

The ¹⁵N(n, γ) capture state should have J^{π}=0⁻,1⁻ assuming s-wave capture. This decay scheme is unusual because the only primary γ -ray populates the 298.22 keV 3⁻ level with an E2 transition while the expected M1 transitions to levels at 0(2⁻)-, 120.42(0⁻)-, and 397.27(1⁻)-keV level are not observed.

The γ -ray cross sections in Table IV were standardized with respect to the 2223 keV γ -ray from hydrogen and corrected for abundance in the ¹⁵N enriched pyridine sample. Total radiative neutron cross sections were determined for each transition in Table IV leading to a consistent set of values. The weighted average total cross section was determined as $\sigma_0(^{15}N)=39.6\pm1.4 \ \mu$ b. Here the uncertainty is nearly entirely statistical. This value is larger than the Mughabghab's compiled value, $\sigma_0(^{15}N)=24\pm8 \ \mu$ b [16], although no primary reference is given. Another measurement reported by Ferguson and Montague [25] gave $\sigma_0(^{15}N)=62\pm6 \ \mu$ b, after correction for a more recent $^{37}Cl(n,\gamma)$ calibration cross section, is larger than our value but does not appear to have been included in the compilation.

C. 12 C cross section

Graphite powder was irradiated for 35,903 s in the cold beam at the Budapest Reactor and six γ -rays were assigned to the ${}^{12}C(n,\gamma)$ reaction whose energies and intensities are summarized in Table V. The ${}^{12}C(n,\gamma)$ level scheme drawing is shown in Fig. 3. Transition probabilities were fit to the level scheme with a $\chi^2/f=0.33$. The neutron separation energy $S_n=4946.32\pm0.06$ keV is in excellent agreement with the recommended value of $S_n=4946.3084\pm0.0005$ keV [10].

The cross section for the 4945.30 keV γ -ray was standardized with respect to the 2223 keV γ -ray from hydrogen and the 1885 keV γ -ray from nitrogen with five stoichiometric compounds as shown in Table VI. We adopt a total cross section $\sigma_0(^{12}\text{C})=3.87\pm0.03$ mb including a statistical uncertainty of 0.03 mb and a standardization uncertainty of 0.01 mb.

There has been considerable variation in the measured ${}^{12}C(n,\gamma)$ cross sections in the past as shown in Table VII. The value $\sigma_0=3.53\pm0.07$ mb, adopted by

FIG. 3: Decay scheme for ${}^{12}C(n,\gamma)$. Total transition probabilities, $P_{\gamma+e}$, are shown. The fit of the γ -rays to the level scheme gives $\chi^2/f=0.6$.

D. 13 **C** cross section

We irradiated a urea target (CH₄N₂O) enriched to 99.5% in ¹³C and 99.1% in ¹⁵N in the cold neutron beam at the Budapest Reactor and seven γ -rays were assigned to the ¹²C(n, γ) reaction whose energies and intensities are summarized in Table VIII and on the level scheme drawing in Fig. 4. The transition probabilities were fit to the level scheme with a $\chi^2/f=1.1$. An additional weak 6587.93 keV E0 transition was placed in the level scheme based on the evaluation of Ajzenberg-Selove [12]. The neutron separation energy $S_n=8176.61(8)$ keV is slightly higher than the recommended value $S_n=8176.43$ keV [10].

FIG. 4: Decay scheme for ${}^{13}C(n,\gamma)$. Total transition probabilities, $P_{\gamma+e}$, are shown. The fit of the γ -rays to the level scheme gives $\chi^2/f=0.01$.

The 6092.46- and 8174.04-keV γ -ray cross sections were standardized relative to the 2223-keV γ -ray from hydrogen in the urea sample as summarized in Table IX. Three separate measurements were made that give a weighted average cross section $\sigma_0(^{13}\text{C})=1.496\pm0.018$ mb. The uncertainty consists of a statistical contribution of 0.018 mb and a standardization contribution of 0.003 mb.

Our result is compared with previous measurements in Table X. The only previous precise measurement was by Mughabghab *et al.* [37] and is $\approx 9\%$ lower than our

^{*a*} Recalculated assuming $\sigma_0(^{12}\text{C})=3.87\pm0.03$ mb, from this work, and $\sigma_0(^{13}\text{C})/\sigma_0(^{12}\text{C})=0.388\pm0.010$ [37].

result. They measured $\sigma_0(^{13}\text{C})/\sigma_0(^{12}\text{C})=0.388\pm0.010$ which, when combined with our new ¹²C cross section, gives $\sigma_0(^{13}\text{C})=1.502\pm0.027$ mb in excellent agreement with our $\sigma_0(^{13}\text{C})$ measurement.

E. ¹⁰B cross section

The ¹⁰B transition γ -ray cross sections were measured on H₃BO₃ and B₄N targets and standardized with respect to the hydrogen and nitrogen γ -ray cross sections respectively. This standardization was done assuming the natural abundance of ¹⁰B is 19.9±0.7%. The hydro-

FIG. 5: Decay scheme for ${}^{10}B(n,\gamma)$. Total transition probabilities, $P_{\gamma+e}$, are shown. The fit of the γ -rays to the level scheme gives $\chi^2/f=2.4$.

gen stoichiometry was corrected for an 0.5% background from water in the sample based on the relative intensity of the 2223-keV hydrogen γ -ray with respect to the intense 478-keV γ -ray from the ¹⁰B(n, α) reaction assuming $\sigma_{\gamma}(478)=719\pm5$ b [16, 40].

The ¹⁰B(n, γ) transition energies and intensities are summarized in Table XI and the ¹¹B decay scheme is shown in Fig. 5. The transition probabilities were fit to the level scheme with a $\chi^2/f=1.4$. In Table XI we have averaged our transition energies and intensities with the previously published data of Kok *et al.* [38]. The neutron separation energy determine in our work, $S_n=11454.02\pm0.10$ keV, is in excellent agreement with the adopted value, $S_n=11454.12\pm0.16$ keV [10].

FIG. 6: Decay scheme for ¹¹B(n, γ). Total transition probabilities, P_{$\gamma+e$}, are shown. The fit of the γ -rays to the level scheme gives $\chi^2/f=0.3$.

The γ -ray cross sections were determined for all transitions in our work relative to hydrogen and nitrogen and are summarized in Table XII. We determined the total cross sections $\sigma_0(^{10}\text{B})$ from the weighted average γ ray cross sections and transition probabilities according to Eq. 1. Agreement between the two calibrations and was good and we get a weighted average cross section $\sigma_0(^{11}\text{B})=394\pm15$ mb. The error is comprised of 6 mb statistical uncertainty, 0.8 mb calibration uncertainty, and 14 mb uncertainty in the abundance of ^{10}B . This result agrees with the earlier measurement by Bartholomew and Campion [19] (500±200 mb) but is higher than the value

F. ¹¹B cross section

¹²B transition probabilities and cross sections from ¹¹B(n, γ) are summarized in Table XIII and the ¹²B decay scheme is shown in Fig. 6. Transition probabilities were fit to the level scheme with a $\chi^2/f=0.01$.

The neutron separation energy was determined as 3368.87 ± 0.16 keV, which is consistent with the recommended value of 3369.8 ± 1.4 keV [10]. The total thermal radiative neutron cross section was determined with respect to the 2223-keV γ -ray from hydrogen as $\sigma_0=9.09\pm0.10$ mb including a statistical uncertainty 0.06 mb, a standardization uncertainty of 0.02 mb, and an uncertainty from the abundance of 0.08 mb. This result is consistent with and more precise than the only other measurement $\sigma_0=5\pm3$ mb, by Imhof *et*

FIG. 7: ¹²B β^- decay scheme. The level at 12 MeV represents β^- decay feeding to a continuum of levels near that energy. Total transition intensities, $P_{\gamma+e}$, are shown.

TABLE XIII: ¹¹B(n, γ) energies and transition probabilities were measured on a natural H₃BO₃ target. The weighted average includes a statistical uncertainty of 0.06 mb with $\chi^2/f=0.02$, a standardization uncertainty of 0.02 mb, and an uncertainty from the ¹¹B abundance of 0.08 mb.

^{*a*} From the evaluation of Ajzenberg-Selove [42].

al. [41], and the recommended value $\sigma_0=5.5\pm3.3$ mb by Mughabghab [16].

¹²B also β^- decays with a half-life of 20.20±0.02 ms [43]. Two γ -rays were observed from this decay at 3214.8 keV, with $\sigma_{\gamma}=74\pm16 \ \mu$ b, and 4438.0 keV, with $\sigma_{\gamma}=81\pm18 \ \mu$ b. The β -decay transition probabilities can be calculated from the ratios of their cross sections to the total radiative neutron cross section, σ_0 , leading to the ¹²B β^- decay scheme shown in Fig. 7. The β -decay feeding to the 7654.2 keV level is $0.81\pm0.18\%$, which is slightly larger than the value $0.58\pm0.02\%$ measured by Hildegaard *et al.* [44] but lower than the evaluated value by Tilley *et al.* of $1.5\pm0.3\%$ [43]. We set an upper limit

G. ⁹Be cross section

The ⁹Be(n, γ) transition probabilities and cross sections were measured on a block of pure beryllium and are summarized in Table XIV and the ¹⁰Be thermal neutron decay scheme is shown in Fig. 8. Transition probabilities were fit to the decay scheme with a $\chi^2/f=0.16$. The ¹⁰Be neutron separation energy measure was determined as 6812.13±0.04 keV, which is slightly lower than the recommended value [10] of 6812.28±0.05 keV.

The γ -ray cross sections were measured with a natural Be(NO₃)₂ target and standardized with respect to nitrogen. Five ¹⁰Be γ -ray cross sections that were measured

FIG. 8: Decay scheme for $^9\mathrm{Be}(\mathrm{n},\gamma).$ Total transition intensities, $\mathrm{P}_{\gamma+e},$ are shown. The fit of the $\gamma\text{-rays}$ to the level scheme gives $\chi^2/\mathrm{f}{=}1.0.$

with high precision in this work are summarized in Table XIV. Total thermal radiative neutron cross sections were determined from each of these transitions giving a weighted average cross section $\sigma_0({}^9\text{Be})=8.27\pm0.13$ mb. The error consists of 0.12 mb statistical uncertainty and 0.03 mb calibration uncertainty. This value is consistent with previous measurements and the adopted value from Mughabghab [16] that are summarized in Table XV.

H. ^{6,7}Li cross sections

The 6,7 Li cross sections were measured with a 7 LiF target enriched to 98% in 7 Li and a natural Li₂CO₃ target. The γ -ray energies, intensities and transition probabilities for both reactions are summarized in Table XVI

TABLE XVI: ${}^{6,7}\text{Li}(n,\gamma)$ energies, intensities, and γ -ray cross sections measured on a LiF target enriched to 98% in ${}^{7}\text{Li}$ and a natural Li₂CO₃ target. Three separate measurements were performed on the Li₂CO₃ target.

mended value [10] of $S_n = 7251.09 \pm 0.01$ keV, and the neutron separation energy for ⁸Li was determined as 2032.564 ± 0.019 keV, consistent with the recommended value of 2032.52 ± 0.05 keV. The cross sections were standardized with respect to the 1633-keV γ -ray from ²⁰F decay in the ⁷LiF target, assuming a cross section of 9.32 ± 0.22 mb [58], and the 4945-keV γ -ray in the Li₂CO₃ target. The γ -ray transition probabilities and cross sections measured in these experiments are summarized in Table XVI. For ⁶Li we obtained $\sigma_0=39.3\pm0.7$ mb with a statistical uncertainty of 0.6 mb, a standardization uncertainty of 0.2 mb, and an uncertainty in the abundance of 0.2 mb. For ⁷Li we obtained $\sigma_0=44.3\pm0.5$ mb with an 0.4 mb statistical uncertainty, 0.3 mb standardization uncertainty, and 0.02 mb uncertainty in the abundance. These values are consistent with previous measurements summarized in Table XVII.

cross sections for the isotopic targets 6,7 Li, 9 Be, 10,11 B, 12,13 C, and 14,15 N have been measured in this work, These cross sections, summarized in Table XVIII, are the result of multiple measurements with multiple standards. They are generally more precise and frequently in significant disagreement with the earlier recommended values of Mughabghab [16]. We have established a new method of determining transition probabilities that incorporate the constraints of the level scheme for these complete capture γ -ray measurements.
