In Ref. [1], K. Tanabe and K. Sugawara-Tanabe claim that the transverse wobbling mode, suggested in Ref. [2], does not exist. In Refs. [1, 3] they suggest an alternative model to explain the observed rotational bands. This comment exposes my concerns about their work.

The appearance of wobbling excitations has been suggested as a hallmark for quantal rotation of triaxial nuclei [4]. Experimental evidence for wobbling in the presence of an odd \(1\text{h}_{11/2}\) proton has been found in \(^{163}\text{Lu}\) [6] and in the presence of an odd \(1\text{h}_{11/2}\) proton in \(^{135}\text{Pr}\) [7]. The observations have been interpreted by coupling the odd proton with a triaxial rotor that describes the even-even core [1-3, 7, 8]. The description sensitively depends on the ratios between the three moments of inertia of the triaxial rotor. These ratios are restricted by the indistinguishability of the protons and neutrons which constitute the rotor core. Quantal rotation about a symmetry axis is not possible [4], i.e., the moment of inertia of a symmetry axis is zero. More generally, the larger the deviation of the density distribution from symmetry with respect to one of its principal axes the larger the moment of inertia. This implies that the medium axis has the largest moment of inertia. This fundamental property of the quantal many body system is in stark contrast with the classical rigid body values of the moments of inertia of the triaxial density distribution

\[
J_k^{rig} = J_0 \left[ 1 - \beta \left( \frac{5}{4\pi} \right)^{1/2} \cos \left( \frac{\gamma + 2\pi k}{3} \right) \right], \quad (1)
\]

while the irrotational flow values of an ideal liquid,

\[
J_k^{hyd} = \frac{15}{4\pi} J_0 \beta^2 \sin^2 \left( \frac{\gamma + 2\pi k}{3} \right), \quad (2)
\]

are in accordance (\(\beta\) and \(\gamma\) are the standard deformation parameters in Lund convention [4]). Here \(J_0 = (5/3)MR^2/3\) is the moment of inertia of a rigid sphere. Its value is not relevant for the following, only the ratios between the three moments are important.

Fig. 1 shows the ratios given by two expressions as functions of the triaxiality parameter. Also shown are the ratios calculated by means of the microscopic cranking model [9] based on the modified oscillator potential. Calculations based on the Woods-Saxon potential give essentially the same results. The microscopic ratios follow the irrotational ones, where the moment of inertia of the short axes is systematically larger. The deviation increases with reduction of the pair correlations. It is to be underlined that without pairing the ratios strongly deviate from the rigid body ones, such that they are in accordance with the fundamental properties of the system that require a zero moment of inertia for a symmetry axis. The systematic study of the \(2^+_1\) states in even-even nuclei by Allmond and Wood [10] provides experimental evidence for a \(\gamma\) dependence of the moment of inertia ratios that is close to the irrotational flow one (2) shown in Fig. 1 (a), where \(J_0\) is about one half of the rigid sphere value. The lower value is attributed to pair correlations [4] and shell structure [5].

Frauendorf and Dönaau [2] classified the particle-triaxial rotor system as, respectively, transverse or longitudinal when the triaxial potential of the rotor aligns the angular momentum of the particle with a principal axes that is perpendicular to or parallel with the axis with the largest moment of inertia. Transversality or longitudinality are reflected by a respective decrease or increase of the excitation energy of the wobbling band with the total angular momentum of the system. Accordingly, \(^{160}\text{Lu}\) and \(^{135}\text{Pr}\) are transverse, because the odd proton’s angular momentum tends to be aligned with the short axis while the medium axis has the maximal moment of inertia. Using the order \(J_m > J_s > J_l\) found by the microscopic calculations, Frauendorf and Dönaau were able to account for the observed energies and transition probabilities.

For their version of the particle-triaxial-rotor model [1,3], Tanabe and Sugawara-Tanabe assume the rigid body ratios (1), which assign the largest moment of inertia to the short axis. This scenario (longitudinal according to [2]) results in an increase of the wobbling frequency with angular momentum. An angular momentum dependent scaling factor is multiplied to all three moments of inertia, such that the experimentally observed decrease of the wobbling frequency is achieved. Adjusting the triaxiality parameter \(\gamma\) the authors are able to fairly well describe the experimental information on transition probabilities. However, the striking contradiction with the preceding discussion of the ratios between the three moments of inertia raises serious concerns about the suggested scenario. As seen in Fig. 1 (c), the three rigid body moments of inertia are almost the same for the core of \(^{135}\text{Pr}\). The \(\gamma\) dependence of the rigid-body moments of inertia is obviously wrong for weakly triaxial and axial nuclei.

In Ref. [1], Tanabe and Sugawara-Tanabe use a small amplitude approximation to the full particle rotor system to study the stability of transverse wobbling for irrotational flow ratios between the moments of inertia. They
conclude with: "There is no wobbling mode around the axis with medium MoI in the particle-rotor model even with the hydrodynamical MoI..." (that is no transverse wobbling). Such a general conclusion is incorrect. The authors considered only weakly deformed nuclei as $^{135}$Pr, for which they find instability of transverse wobbling for $I > 13/2$. In Ref. [2], Frauendorf and Dönau estimated the critical angular momentum $J_c$ where transverse wobbling becomes unstable assuming that the angular momentum of the odd particle $j$ is aligned with the short axis ("frozen alignment approximation").

$$J_c = j \frac{J_m}{J_m - J_s}. \tag{3}$$

For $j = 11/2$ and the ratio $J_m/J_s = 4$ by Eq. (2) at $\gamma = 30^\circ$, the estimate gives instability for $I > J_c \approx 15/2$, where for the exact particle rotor solution transverse wobbling becomes only unstable for $I > 19/2$ (see Fig. 16 of [2]). That is, the small-amplitude expression in Ref. [1] underestimates the critical angular momentum $J_c$. More important, when the moment of inertia of the short axis is increased to $J_s = 0.6J_m$ the frozen alignment estimate (3) gives $J_c = 27/2$. Accordingly, the instability moves up to $I = 29/2$ for the exact particle rotor calculation, where it is observed in experiment (see Fig. 15 of [2]).

The microscopic calculations indicate a larger moment of inertia of the short axis than irrotational flow. The full particle rotor calculations give stable transverse wobbling for the strongly deformed nucleus $^{163}$Lu for both irrotational flow and microscopic moments of inertia.

To summarize, stable transverse wobbling does exist and the assumption of rigid body ratios between the moments of inertia of the triaxial rotor core in Refs. [1, 3] contradicts basic concepts of quantal rotation.

![Graphs showing moments of inertia as a function of the triaxiality parameter $\gamma$.](image) FIG. 1: The moments of inertia of the three principal axes as function of the triaxiality parameter $\gamma$. Thick black curves: irrotational flow values Eq. (2); thick dashed curves: rigid body values Eq. (1); colored (grey) curves: microscopic values obtained by cranking calculations. In panel (a) "hydro" denotes the irrotational flow values and "cranking" the cranking values, which are scaled by the factor $J_{m,\text{crank}}(\gamma)/J_{m,\text{hydro}}(\gamma)$. The numbers in the legends quote the pairing strength. $J_{1110}$ means $\Delta_p = 1.1\text{MeV}, \Delta_n = 1.0\text{MeV}$; $J_{0309}$ means $\Delta_p = 0.3\text{MeV}, \Delta_n = 0.9\text{MeV}$; etc. Panels (a) and (b) show the same calculations for $Z = 68, N = 96, \varepsilon = 0.25$; panel (c) for $Z = 38, N = 76, \varepsilon = 0.2$; and panel (d) for $Z = 68, N = 96, \varepsilon = 0.4$. In panels (b-d) the three moments of inertia are shown in the three $\gamma$ intervals: long $-120^\circ \leq \gamma \leq -60^\circ$, with $\gamma \to \gamma + 120^\circ$; medium $-60^\circ \leq \gamma \leq 0^\circ$, with $\gamma \to -\gamma$; short $0^\circ \leq \gamma \leq 60^\circ$; compare (a) with (b). The intersections of the red (grey) vertical lines indicate the moments of inertia of the three axes for $\gamma = 20^\circ$. 

- **(a)** shows the irrotational flow (hydro) and cranking (cranking) moments of inertia for $Z = 68, N = 96$.
- **(b)** shows the irrotational flow (hydro) and cranking (cranking) moments of inertia for $Z = 38, N = 76$.
- **(c)** shows the irrotational flow (hydro) and cranking (cranking) moments of inertia for $Z = 68, N = 96$.
- **(d)** shows the irrotational flow (hydro) and cranking (cranking) moments of inertia for $Z = 68, N = 96$.
