The lifetime of the  $B_c^-$  meson is measured using 272 exclusive  $B_c^- \rightarrow J/\psi(\rightarrow \mu^+\mu^-) \pi^-$  decays reconstructed in data from proton-antiproton collisions corresponding to an integrated luminosity of  $6.7 \text{ fb}^{-1}$  recorded by the CDF II detector at the Fermilab Tevatron. The lifetime of the  $B_c^-$  meson is measured to be  $\tau(B_c^-) = 0.452 \pm 0.048(\text{stat}) \pm 0.027(\text{syst}) \text{ ps}$ . This is the first measurement of the  $B_c^-$  meson lifetime in a fully-reconstructed hadronic channel, and it agrees with previous results and has comparable precision.

PACS numbers: 14.40.Nd, 13.25.Hw

In the standard model the  $B_c^-$  meson is the only meson composed of two distinct heavy quarks. The  $B_c^-$  meson decay can be governed by the decay of the  $b$  or  $\bar{c}$  spectator quarks or can proceed through the annihilation of the  $b$  and  $\bar{c}$  quarks. Various theoretical techniques have been used to predict the  $B_c^-$  meson lifetime. An operator-product-expansion calculation [1] predicts a  $B_c^-$  meson lifetime in the range of 0.4 to 0.7 ps. A QCD sum rule approach [2] predicts the lifetime to be  $0.48 \pm 0.05 \text{ ps}$ . Another approach [3], estimating the  $B_c^-$  meson lifetime by global fitting of the phenomenological parameters of all other heavy mesons, gives a result of 0.36 or 0.47 ps, depending on different choices of effective heavy-quark masses.

The  $B_c^-$  meson lifetime was measured previously in semileptonic decays by CDF [4] and D0 [5]. These measurements have an undetected neutrino in the final state and rely on the modeling of the  $B_c^-$  meson momentum to account for unmeasured momentum of the neutrino. Therefore, a measurement of the  $B_c^-$  meson lifetime in a fully-reconstructed decay mode is desired since it does not suffer from this limitation. CDF is the first experiment to observe the fully-reconstructed  $B_c^- \rightarrow J/\psi(\rightarrow \mu^+\mu^-) \pi^-$  decay mode [6] and to measure the  $B_c^-$  mass [7]. In this paper we present a lifetime measurement of the  $B_c^-$  meson using this decay mode. This measurement is made using data from  $p\bar{p}$  collisions at a center-of-mass energy of 1.96 TeV recorded by the Collider Detector at Fermilab (CDF II). The results are based on a data sample with an integrated luminosity of  $6.7 \text{ fb}^{-1}$ .

The components of the CDF II detector [8] most relevant for this analysis are the charged-particle tracking and muon identification systems. The tracking system is immersed in a uniform 1.4 T solenoidal magnetic field coaxial with the beam line, and consists of single- and double-sided silicon detectors [9] and a 96-layer open-cell drift chamber (COT) [10]. The muon system is used to identify the  $J/\psi \rightarrow \mu^+\mu^-$  decay. Two sets of muon chambers [11, 12] are used to cover different pseudorapidity regions.

A three-level event-selection system (trigger) is used to collect events enriched in  $J/\psi \rightarrow \mu^+\mu^-$  decays [8]. The event reconstruction starts by combining two muon candidates to form a  $J/\psi$  candidate. The trigger requirements are confirmed by selecting events that contain two oppositely charged muon candidates, each with matching COT and muon chamber tracks. The muon-pair mass is required to be within  $80 \text{ MeV}/c^2$  of the world-average  $J/\psi$  mass [13], where the mass resolution is  $13 \text{ MeV}/c^2$ .

Both  $J/\psi K^-$  and  $J/\psi \pi^-$  combinations are reconstructed in this analysis. The large  $B^- \rightarrow J/\psi K^-$  sample is used as a reference decay for  $B_c^- \rightarrow J/\psi \pi^-$ . These final states are identified by assigning the  $K^-$  or  $\pi^-$  mass to other reconstructed tracks not used in the  $J/\psi$  candidates and forming  $B^-$  or  $B_c^-$  candidates. Each three-track combination must satisfy a kinematic fit in which the three tracks are required to originate from a common decay point, and the invariant mass of the muon pair is constrained to the world-average  $J/\psi$  mass [13]. The  $K^-$  and  $\pi^-$  candidate track is named the third track  $h^-$ . A minimal selection is made on kinematic quantities

after the constrained fit including  $p_T(h^-) > 1.7$  GeV/ $c$  and  $p_T(B) > 5$  GeV/ $c$ , where  $p_T$  is the momentum component transverse to the beam line, and  $B$  refers to a  $J/\psi$   $h^-$  candidate. The selection criteria for the  $B$  candidates are listed in Table I and discussed below.

TABLE I. Selection requirements.

Selection variable	Requirement
$p_T(h^-)$	$> 2.0$ GeV/ $c$
$p_T(B)$	$> 6.5$ GeV/ $c$
$P(\chi^2)$	$> 0.1\%$
$ d(B) /\sigma_{d(B)}$	$< 2.0$
$\beta_T$	$< 0.2$ radians
$I_B$	$> 0.6$
$\sigma_m(B)$	$< 40$ MeV/ $c^2$
$ct$	$> 80$ $\mu\text{m}$
$\sigma_{ct}(B)$	$< \max[35, 65 - 3 p_T(B)(\text{GeV}/c)] \mu\text{m}$

The  $h^-$  and  $B$  candidates are required to have a minimum  $p_T$  to suppress combinatorial background events. We reject events with poorly defined decay points by imposing a lower threshold to the chi-square probability  $P(\chi^2)$  of the constrained fit used to reconstruct the  $B$  candidates. We select  $B$  candidates that originate from the primary interaction point by requiring a small impact parameter  $d(B)$  (transverse distance of closest approach to the beam line) in units of its uncertainty  $\sigma_{d(B)}$  and a small angle  $\beta_T$  between  $\vec{L}_T$  and  $\vec{p}_T(B)$ , where  $\vec{L}_T$  is the transverse displacement vector from the primary interaction point to the  $B$ -decay point, and  $\vec{p}_T(B)$  denotes a vector in the transverse plane along the momentum direction of the  $B$  candidate. The isolation  $I_B$  of the  $B$  candidate is defined as  $I_B \equiv p(B)/(p(B) + |\sum_i \vec{p}_i|)$ , where  $\sum_i \vec{p}_i$  is the sum of momenta over all other reconstructed tracks not used in the  $J/\psi$   $h^-$  combination within  $\sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.7$ , and  $\Delta\eta$  and  $\Delta\phi$  are the differences in pseudorapidities and azimuthal angles of tracks relative to  $\vec{p}(B)$ . We also suppress the promptly produced combinatorial background by rejecting candidates with small  $ct$ , where  $ct$  is the decay length of the  $B$  candidate determined by

$$ct \equiv \vec{L}_T \cdot \vec{p}_T(B) \frac{c m(B)}{|p_T(B)|^2}, \quad (1)$$

and  $m(B)$  is the reconstructed mass of the  $B$  candidate. Requirements on  $\sigma_m(B)$  and  $\sigma_{ct}(B)$  are made to reject poorly reconstructed events, where  $\sigma_m(B)$  and  $\sigma_{ct}(B)$  are the associated uncertainties from the kinematic fit of  $m(B)$  and  $ct(B)$ , respectively. The optimization of the selection requirements is obtained by maximizing the quantity  $\mathcal{S}/\sqrt{(\mathcal{S} + \mathcal{B})}$  where the background  $\mathcal{B}$  is estimated from the mass sidebands in data and the signal  $\mathcal{S}$  is estimated from the signal-region data after subtracting background contributions as calculated from sidebands.

Because the  $\sigma_{ct}(B)$  distribution depends on  $p_T(B)$ , we vary the requirement on  $\sigma_{ct}(B)$  as a function of  $p_T(B)$ .

FIG. 1. Invariant-mass distribution of  $J/\psi$   $K^-$  candidates. The hatched areas are the sideband regions and the signal region lies between them.

For candidates with  $p_T(B) < 10$  GeV/ $c$ , we require  $\sigma_{ct}(B) < (65 - 3 p_T(B)) \mu\text{m}$  for  $p_T(B)$  measured in GeV/ $c$ , and  $\sigma_{ct}(B) < 35 \mu\text{m}$  for  $p_T(B) \geq 10$  GeV/ $c$ . This  $p_T$ -dependent requirement on  $\sigma_{ct}(B)$  is chosen to be highly efficient for preserving signal while reducing combinatorial background and leads to no measurable biases.

The resulting  $B^-$  mass distribution is shown in Fig. 1. The signal region lies between two background sideband regions and has 46 280  $B^-$  candidates. The two sideband regions consist of a lower sideband from 5.18 to 5.23 GeV/ $c^2$  and an upper sideband from 5.33 to 5.38 GeV/ $c^2$ , as shown in the hatched areas.

The  $B_c^- \rightarrow J/\psi \pi^-$  candidates are formed from the same parent sample as the  $B^- \rightarrow J/\psi K^-$  candidates where the only change to the reconstruction is to assign the pion mass to the third track. We then select events for further analysis using the selections in Table I. The reconstructed mass distribution for the  $B_c^-$  candidates is shown in Fig. 2. The signal region lies between two background sideband regions and has 1496  $B_c^-$  candidates. The two sideband regions of  $B_c^-$  candidates consist of a lower sideband from 6.16 to 6.21 GeV/ $c^2$  and an upper sideband from 6.33 to 6.60 GeV/ $c^2$ , as shown in the hatched areas. The lower sideband is narrow to avoid contamination from semileptonic  $B_c^-$  decays where the lepton is misidentified as a pion.

We generate Monte Carlo simulations for  $B^- \rightarrow J/\psi K^-$  and  $B_c^- \rightarrow J/\psi \pi^-$  decays to study the efficiency of the selection criteria as a function of decay length. The Fixed-Order plus Next-to-Leading Logarithms (FONLL)  $p_T$  spectrum [14] is used for the  $B^-$  production spectrum. We use the calculation of Ref [15] as the spectrum for  $B_c^-$  simulation. In comparing the FONLL  $p_T$  spectrum for  $B^-$  production with the experimental data, reasonable consistency is observed for  $p_T > 6$  GeV/ $c$ , and any residual discrepancy gives a negligible systematic uncertainty. To further

FIG. 2. Invariant-mass distribution of  $J/\psi \pi^-$  candidates. The hatched areas are the sideband regions and the signal region lies between them. The fit result is overlaid in the signal region, as well as the signal and background components.

FIG. 3. The  $\sigma_{ct}$  distribution of  $J/\psi K^-$  candidates obtained from the simulation is compared with data.

validate the  $B^- \rightarrow J/\psi K^-$  simulation, we compare the distributions of the selection variables listed in Table I for experimental data and simulation. Generally, good agreement is observed for all selection variables except for  $\sigma_{ct}(B)$ , whose comparison is shown in Fig. 3. The disagreement in the  $\sigma_{ct}(B)$  distribution arises from mis-modeling of the silicon tracking detector in the simulation, giving a smaller  $\sigma_{ct}(B)$  compared with experimental data for a given  $p_T(B)$ . Consequently, the selection requirement made on  $\sigma_{ct}(B)$  for simulation is tuned in order to allow the same efficiency as in the experimental data. These  $\sigma_{ct}(B)$  selection values for simulation are also  $p_T$ -dependent, and the  $p_T$  thresh-

old remains the same; the only change is to require  $\sigma_{ct}(B) < (45 - 2 p_T(B)) \mu\text{m}$  for  $p_T(B) < 10 \text{ GeV}/c$ , and  $\sigma_{ct}(B) < 25 \mu\text{m}$  for  $p_T(B) \geq 10 \text{ GeV}/c$ . The systematic uncertainty associated with the tuning will

FIG. 4. Comparison of efficiency for  $B^- \rightarrow J/\psi K^-$  obtained from data and the fit result from simulation. Also shown is the fit result for  $B_c^- \rightarrow J/\psi \pi^-$  simulation.

be discussed later.

The efficiency of the selection criteria is found by comparing the decay-length distribution after applying the selection in Table I to that obtained from the minimal selection which requires  $p_T(h^-) > 1.7 \text{ GeV}/c$  and  $p_T(B) > 5 \text{ GeV}/c$ . The efficiency determined from simulation is then fit to a function of the form

$$\epsilon(ct) = C \left[ 1 - \exp\left(-\frac{a - ct}{b}\right) \right], \quad (2)$$

where  $C$ ,  $a$ ,  $b$  are parameters to be fit. Figure 4 shows the efficiency determined from  $B^- \rightarrow J/\psi K^-$  experimental data as well as the fit result from simulation. The parameter  $C$  in Eq. (2) is not necessary in the lifetime fit because only the relative shape of the efficiency function matters. The requirement on  $\beta_T$  leads to an efficiency that is not constant as a function of decay length. This variable is very effective in rejecting background events, especially for events with small  $ct$ . The good agreement between the simulated efficiency and the data-determined efficiency supports the use of this approach in the  $ct$ -dependent efficiency. The efficiency for the  $B_c^- \rightarrow J/\psi \pi^-$  decay as a function of decay time determined from simulation is fit and also shown in Fig. 4.

We use a maximum log-likelihood simultaneous fit to the unbinned mass and decay-length distributions of the  $B_c^-$  candidates. The likelihood function consists of signal and background parts, and each part has a mass term and a decay length term. The log-likelihood function is

$$\ln \mathcal{L} = \sum_i \ln [f_s M_s(m_i) T_s(ct_i) + (1 - f_s) M_b(m_i) T_b(ct_i)], \quad (3)$$

where  $f_s$  is the signal fraction,  $m_i$  and  $ct_i$  are the reconstructed mass and decay length for event  $i$ .  $M_s(m_i)$  and  $T_s(ct_i)$  are the normalized probability density functions for mass and decay length of the signal model, and  $M_b(m_i)$  and  $T_b(ct_i)$  are the corresponding functions of the background model. The signal mass model  $M_s(m_i)$  is described by a Gaussian distribution with mean  $m_0$  and width  $\sigma_m$ , whose values are determined by the fit. The signal decay length model  $T_s(ct_i)$  is an exponential distribution with characteristic lifetime  $\tau$ , smeared by the detector resolution and multiplied by the efficiency function given in Eq. (2). The detector resolution, which is modeled as a Gaussian distribution centered at zero with a width of  $20 \mu\text{m}$ , is chosen to be consistent with calibration using promptly decaying background events [16]. The background mass model  $M_b(m_i)$  is described by a linear distribution, and  $T_b(ct_i)$  is described by a linear combination of three exponential distributions.

A two-step process is used to extract the lifetime of the  $B_c^-$  meson. The first step includes the efficiency fit and the sideband fit. The efficiency fit is performed on the simulated events using Eq. (2), and the result is shown in Fig. 4. The sideband fit consists of two separate fits in the sideband regions. The first fit determines the background mass model parameters, and the second fit determines the background decay-time model parameters. The signal region is fit with the efficiency and background parameters Gaussian-constrained to the result of the earlier fits. The signal fraction and the signal model parameters are allowed to float freely in maximizing the log-likelihood function given in Eq. (3).

To validate this fitting technique, the fit is first applied to the  $B^-$  candidates shown in Fig. 1 to extract the  $B^-$  meson lifetime. The  $B^-$  lifetime which is found to be  $\tau(B^-) = 1.637 \pm 0.010$  (stat) ps is in agreement with the world-average value of  $1.641 \pm 0.008$  ps [13]. The  $B^-$  signal yield returned from the fit is  $43\,308 \pm 171$ . The fit is then applied to the  $B_c^-$  candidates shown in Fig. 2, resulting in a lifetime of  $\tau(B_c^-) = 0.452 \pm 0.048$  (stat) ps for the  $B_c^-$  meson, which is taken as our central result, with a  $B_c^-$  signal yield of  $272 \pm 61$  (stat) candidates. The  $B_c^-$  meson mass of  $6274.6 \pm 2.9$  (stat)  $\text{MeV}/c^2$  returned from the fit is in good agreement with previous the CDF determination [7]. Figures 2 and 5 show the distribution of the  $J/\psi \pi^-$  mass and decay length. The fit projections are overlaid.

We have considered several sources of systematic uncertainty and evaluated their contributions. To evaluate possible systematic uncertainties with the models in the likelihood function, we generate 400 simulated data samples (pseudoeperiments) whose distributions are based on the fit results determined by the experimental data. These pseudoeperiments are then fit with the default

FIG. 5. Decay-length distribution of  $J/\psi \pi^-$  candidates. The fit projection, along individual contributions from signal and background, is overlaid.

and alternate models separately. The distributions of the sample-by-sample lifetime differences between different models are obtained and compared with the differences observed in experimental data. To assess the effect of the choice of the linear model for the mass-fit background, we compare to the result of a fit using a bilinear model that allows the background distribution to have different slopes at masses lower and higher than the  $B_c^-$  pole mass, with the constraint that these two distributions intersect at the fit  $B_c^-$  mass value. The fit lifetime with this bilinear model has a shift of  $-0.009$  ps compared with the default linear model. The pseudoeperiments suggests up to a  $0.017$  ps difference from this variation. We conclude that the shift between the data fits is consistent with the spread among the pseudoeperiments, and we use that larger difference as the systematic uncertainty from the background mass model.

To assess a possible systematic uncertainty due to the modeling of the long tail in the background decay-length distribution, we test an alternate model of the background decay time which uses a linear distribution to replace the component with the largest characteristic lifetime in the three exponential distributions. This variation gives a lifetime result that changes by  $-0.0007$  ps compared with the default background decay-time model. However, fit results from pseudoeperiments suggest the difference between these two models could be  $0.013$  ps, which is included as the systematic uncertainty due to the choice of the background decay-time model.

The signal decay-time model includes the efficiency determined from the simulation. We have performed several studies to estimate the associated systematic un-

certainty. First, the fit is repeated using an efficiency function obtained without tuning the  $\sigma_{ct}(B)$  difference between data and simulation. The difference in the estimated lifetime is 0.003 ps. Second, the efficiency function is shifted toward lower and higher decay length by 20  $\mu\text{m}$  to account for a possible uncertainty in determining the efficiency function parameters; this 20  $\mu\text{m}$  shift is equivalent to three standard deviations of the parameter  $a$  in Eq. (2). This variation gives a difference of  $-0.010$  ( $+0.007$ ) ps for shifting toward lower (higher) decay lengths. The distribution of the difference between the resulting lifetimes in the pseudoexperiments is fit by a Gaussian distribution that centers at  $-0.006$  (0.004) ps with a width of 0.002 (0.001) ps for shifting toward lower (higher) decay lengths. Third, the systematic uncertainty associated with the  $B_c^-$  production spectrum has been assessed. We vary the relative fraction of different contributions to the production spectrum; the difference in the corresponding efficiency is negligible and no systematic uncertainty is assigned to it. Finally, to further study the systematic uncertainty associated with the production spectrum, we use the efficiency parameters obtained from the  $B^- \rightarrow J/\psi K^-$  simulation. Since the  $B^-$  production spectrum is quite different from that of  $B_c^-$ , the fit lifetime difference of 0.007 ps indicates that the production spectrum does not contribute significantly to the systematic uncertainty. Thus, the total systematic uncertainty associated with the signal decay-time model is taken to be 0.010 ps.

Correlations between the lifetime and other parameters of the analysis are considered as possible systematic uncertainties. The list of parameters includes the minimum and maximum decay length for events in the final fit, adding a parameter to the efficiency model, small variations in the sideband definitions, small modifications in the selection requirements, the use of an alternate fit procedure which fits the sideband and the signal regions simultaneously, the mass resolution in the signal model, the background fraction, and the three terms describing the exponentials in the background decay time model. No systematic effect was found to significantly exceed the variations expected from statistical uncertainties. We assign an additional uncertainty of 0.010 ps as a conservative approach to account for possible small systematic effects.

The systematic uncertainty due to tracking detector misalignments is evaluated by generating simulated samples with radial displacements of individual sensors as well as translation and rotation of the silicon detector relative to the COT [17]. A systematic uncertainty of 0.007 ps is assigned to the misalignment based on these simulated samples. The systematic uncertainty from the signal mass model is evaluated by including a contribution to the total  $B_c^-$  signal yield from the Cabibbo-suppressed decay  $B_c^- \rightarrow J/\psi K^-$  in the signal mass shape. The Cabibbo-suppressed contribution is fixed to be 5% of the total  $B_c^-$  signal yield as determined from the Cabibbo angle. This effect results in a 0.003 ps

variation.

The systematic uncertainty from the fitting technique itself is tested by generating pseudoexperiments, and comparing the fit lifetimes with the input lifetime. The bias on the lifetime returned by the fit is found to be no greater than 0.003 ps which we take as systematic uncertainty. Table II summarizes the systematic uncertainties, which are added in quadrature to determine the total systematic uncertainty.

TABLE II. Summary of systematic uncertainties.

Source	Uncertainty [ps]
Background mass model	0.017
Background decay-time model	0.013
Signal decay-time model	0.010
Correlation	0.010
Misalignment	0.007
Signal mass model	0.003
Fitting technique	0.003
Total	0.027

Given that the efficiency is not uniform over decay length, our result relies on the accuracy of the simulation in determining the efficiency. We check our result by measuring the  $B_c^-$  lifetime using a different set of selection criteria, each of which has uniform efficiency in the  $B^- \rightarrow J/\psi K^-$  decay. The most important differences between these selection criteria and those listed in Table I are removing the  $\beta_T$  requirement and using a larger minimum  $ct$  requirement. The alternate selection criteria gives 6538  $B_c^-$  candidates between 6.0 and 6.6  $\text{GeV}/c^2$  which is roughly the same number as obtained from the selections in Table I (6368 candidates), while only 2578 candidates are common to both samples.

The consistency check also uses an unbinned maximum log-likelihood fit to extract the  $B_c^-$  meson lifetime. The signal mass model consists of a Gaussian distribution centered at the  $B_c^-$  meson mass and a Cabibbo-suppressed  $B_c^- \rightarrow J/\psi K^-$  Gaussian distribution centered at 60  $\text{MeV}/c^2$  below the  $B_c^-$  meson mass with a 30  $\text{MeV}/c^2$  width. The signal decay-time model is an exponential distribution convoluted with the detector resolution. The background mass model is described by a linear distribution, and the background decay-time model consists of two prompt Gaussian distributions, two positive exponential distributions, and one negative exponential distribution.

A similar two-step fit is used in the consistency check. The first step is to determine the background parameters from the sideband fit, where the sideband is defined as the  $J/\psi \pi^-$  invariant-mass region between 6.4 and 6.5  $\text{GeV}/c^2$ . The sideband fit is performed on events with decay length between  $-1000$   $\mu\text{m}$  and 1000  $\mu\text{m}$  and the resulting background parameters are fixed in the second step. In the second step we fit events in the signal region between 6.16 and 6.36  $\text{GeV}/c^2$ , and only the signal fraction and signal model parameters

are allowed to float. The consistency check is first performed on the  $B^-$  candidates. The fit result finds the  $B^-$  lifetime to be  $\tau = 1.647 \pm 0.020$  (stat) ps, which agrees with the world-average value of  $1.641 \pm 0.008$  ps [13]. The consistency check is then applied to the  $B_c^-$  candidates, giving a  $B_c^-$  meson lifetime of  $\tau = 0.450 \pm 0.053$  (stat) ps which is consistent with our central value of  $0.452 \pm 0.048$  (stat) ps. The  $B_c^-$  signal yield from the consistency check is  $308 \pm 39$  (stat) which is compared with  $272 \pm 61$  (stat) from the central result. The total systematic uncertainty in the consistency check is 0.033 ps where the largest uncertainty of 0.027 ps comes from the background decay-time model. Thus, we conclude that our central result obtained from the  $ct$ -dependent efficiency is reliable.

In conclusion, we have made the first measurement of the  $B_c^-$  meson lifetime in a fully-reconstructed hadronic decay mode. Using the  $B_c^- \rightarrow J/\psi \pi^-$  decay channel, the lifetime of the  $B_c^-$  meson is measured to be  $\tau = 0.452 \pm 0.048$ (stat)  $\pm 0.027$ (syst) ps. This result is consistent with the most recent result from the D0 col-

laboration [5] using semileptonic decay channels,  $\tau = 0.448^{+0.038}_{-0.036}$ (stat)  $\pm 0.032$ (syst) ps, and has comparable precision. The result also agrees with theoretical calculations in which the decay width of the  $B_c^-$  meson is dominated by the decay of the charm quark.
