(Dated: February 27, 2015)

We present results on the effect of the stiffness of the equation of state on the dynamical bar-mode instability in rapidly rotating polytropic models of neutron stars in full General Relativity. We determine the change in the threshold for the emergence of the instability for a range of the adiabatic Γ index from 2.0 to 3.0, including two values chosen to mimic more realistic equations of state at high densities.

I. INTRODUCTION

Non-axisymmetric deformations of rapidly rotating self-gravitating objects are a generic phenomenon in nature and are expected to appear in a wide range of astrophysical scenarios, like stellar core collapses [1, 2], accretion-induced collapses of white dwarfs [3], or mergers of two neutron stars [4, 5]. Over more than a decade, a considerable amount of work has been devoted to the search of unstable deformations that, even when starting from an axisymmetric configuration, can lead to a highly deformed, rapidly rotating, massive object [6–11]. In the case of neutron stars, such deformations would lead to an intense emission of gravitational waves in the kHz range, potentially detectable on Earth within the next decade [12] by next-generation gravitational-wave detectors such as Advanced LIGO [13], Advanced VIRGO, or KAGRA [14].

Any insight on the possible astrophysical scenarios where such instabilities might be present would aid potential observations and their analysis and understanding. It is well-known that rotating neutron stars are subject to non-axisymmetric instabilities for non-radial axial modes with azimuthal dependence $e^{im\phi}$ (with $m = 1, 2, \ldots$) when the instability parameter $\beta \equiv T/|W|$ (i.e. the ratio between the kinetic rotational energy T and the gravitational potential energy W) exceeds a certain critical value β_c. This instability parameter plays an important role in the study of the so-called dynamical bar-mode instability, i.e. the $m = 2$ instability which takes place when β is larger than the threshold β_c [7]. Previous results for the onset of the classical bar-mode instability have already shown that the critical value β_c for the onset of the instability is not a universal quantity and it is strongly influenced by the rotational profile [15, 16], by relativistic effects [6, 7], and, in a quantitative way, by the compactness [17].

However, until the recent work in [11], significant evidence of their presence when realistic EOSs are considered was missing. For example, in [18], using the unified SLy EOS [19], the presence of a shear-instability was shown, but there was no sign of the classical bar-mode instability and its critical behavior. The aim of the present work is to get more insight into the behavior of the classical bar-mode instability when the matter is described by EOSs with different stiffness. The investigations in the literature into its dependence on the stiffness of EOSs usually focused on values of Γ (i.e. the adiabatic index of a polytropic EOS) in the range from 1 to 2 [9, 10, 20], while the expected value for a real neutron star is more likely higher, between 2 and 3, and probably around $\Gamma = 2.75$ (at least in large portions of the interior). Such a choice for the EOS was already implemented in [21], and also quite recently in [11, 22]. Its benefit is the ability to maintain the simplicity of a polytropic EOS and yet to obtain properties that resemble a more realistic case. Indeed, as it is shown in Fig. 1, (here [CU] stands for normalized computational units, see below) a polytropic EOS with $K = 30000$ [CU] and $\Gamma = 2.75$ is qualitatively similar to the Shen proposal [23, 24] in the density interval between $2 \times 10^{13} \text{g/cm}^3$ and 10^{15}g/cm^3, while a polytropic EOS with $K = 80000$ [CU] and $\Gamma = 3.00$ approximately resembles the SLy EOS for densities higher than $2 \times 10^{14} \text{g/cm}^3$.

The organization of this paper is as follows. In Sec. II we describe the properties of the relativistic stellar models we investigated and briefly review the numerical setup used for their evolutions. In Sec. III we present and discuss our results, showing the features of the evolution and quantifying the effects of the compactness on the onset of the instability. Conclusions are given in Sec. IV. Throughout this paper we use a space-like signature $-, +, +, +$, with Greek indices running from 0 to 3, Latin indices from 1 to 3, and the standard convention
FIG. 1. Diagram of the pressure P vs. the energy density e for all polytropic EOSs considered and two *realistic* EOSs for nuclear matter, namely (1) the Shen proposal [23, 24]; (2) the unified SLy prescription [25]. The polytropic EOS with $\Gamma = 2.75$ is close to the Shen EOS, while the case of $\Gamma = 3.0$ is close to the SLy EOS, both above a certain density.

for summation over repeated indices. All the computation has been done in the normalized computational units [CU] in in which $c = G = M_\odot = 1$. We report all results in cgs units except for values of the polytropic constant K, whose unit of measurement depends on the value of the adimensional polytropic exponent Γ, which is reported in the above defined normalized unit [CU]. We also report masses in terms of the solar mass $M_\odot$.

II. INITIAL MODELS AND NUMERICAL SETUP

We follow the same setup as in [11] (only changing the EOS parameters Γ and K), but for convenience the main ideas are summarized in the following section.

In this work we solve Einstein's field equations

$$G_{\mu\nu} = 8\pi T_{\mu\nu} \,, \tag{1}$$

where $G_{\mu\nu}$ is the Einstein tensor of the four-dimensional metric $g_{\mu\nu}$ and $T^{\mu\nu}$ is the stress-energy tensor of an ideal fluid. The energy-momentum tensor $T^{\mu\nu}$ can be parametrized as

$$T^{\mu\nu} = \rho \left(1 + \epsilon + \frac{P}{\rho} \right) u^\mu u^\nu + P g^{\mu\nu} \,, \tag{2}$$

where ρ is the rest-mass density, ϵ is the specific internal energy of the matter, P is the pressure, and u^μ is the matter 4-velocity. The evolution equations for the matter follow from the conservation laws for the energy-momentum tensor $\nabla_\mu T^{\mu\nu} = 0$ and the baryon number $\nabla_\mu(\rho u^\mu) = 0$, closed by an EOS of the type $P = P(\rho, \epsilon)$.

In order to generate the initial data, we use a Γ-type EOS of the form

$$P = K \rho^\Gamma \,, \tag{3}$$

where the following relation between ϵ and ρ holds: $\epsilon = K\rho^{(\Gamma-1)}/(\Gamma - 1)$. On the other hand, the evolution is performed using the so-called *ideal-fluid* (Γ-law) EOS

$$P = (\Gamma - 1)\rho\epsilon \,, \tag{4}$$

that allows for increase of the internal energy by shock heating, if shocks are present.

We solve the above set of equations using the usual $3 + 1$ space-time decomposition, where the space-time is foliated as a tensor product of a three-space and a time coordinate t (which is selected to be the x^0 coordinate). In this coordinate system the metric can be split as $g^{\mu\nu} = -n^\mu n^\nu + h^{\mu\nu}$, where $h^{\mu\nu}$ has only the spatial components different from zero and can be used to define a Riemannian metric $\gamma^{ij} = h^{ij}$ on each foliation. The vector n^μ, that determines the direction normal to the 3-hypersurfaces of the foliation, is decomposed in terms of the lapse function α and the shift vector β^i, such that $n^\mu = \alpha^{-1} \cdot (1, \beta^i)$. We also define the fluid three-velocity v^i as the velocity measured by a local zero-angular momentum observer ($u^i = \alpha v^i - \beta^i$), while the Lorentz factor is $\alpha u^0 = \sqrt{1 - \gamma_{ij} v^i v^j}$. Within this formalism, the conservation of the baryon number suggests the use of the conserved variable $D = \sqrt{\gamma}\alpha u^0 \rho$ with the property that $\int D\, d^3 x = \text{const}$ along the time-evolution t.

A. Initial Data

The initial data of our simulations are calculated as stationary equilibrium solutions for axisymmetric and rapidly rotating relativistic stars in polar coordinates [26]. We assume that the metric describing the axisymmetric and stationary relativistic star has the form

$$ds^2 = -e^{\mu+\nu}dt^2 + e^{\mu-\nu}r^2 \sin^2\theta(d\phi - \omega dt^2)^2 + e^{2\xi}(dr^2 + r^2 d\theta^2) \,, \tag{5}$$

where μ, ν, ω, and ξ are space-dependent metric functions. Similarly, we assume the matter to be characterized by a non-uniform angular velocity distribution of the form

$$\Omega_c - \Omega = \frac{1}{\hat{A}^2 r_e^2}\left[\frac{(\Omega - \omega)r^2 \sin^2\theta e^{-2\nu}}{1 - (\Omega - \omega)^2 r^2 \sin^2\theta e^{-2\nu}} \right], \tag{6}$$

where r_e is the equatorial stellar coordinate radius, Ω_c is the angular velocity at the center of the star, and the coefficient $\hat{A}$ is the measure of the degree of the differential rotation, which we set to be $\hat{A} = 1$, analogous to works in the literature, and especially [11]. Once imported onto the Cartesian grid, throughout the evolution we compute the coordinate angular velocity Ω on the (x, y) plane as

$$\Omega = \frac{u^\phi}{u^0} = \frac{u^y \cos\phi - u^x \sin\phi}{u^0 \sqrt{x^2 + y^2}} \,. \tag{7}$$

Other characteristic quantities of the system such as the baryon mass M_0, the gravitational mass M, the internal

energy E_{int}, the angular momentum J, the rotational kinetic energy T, the gravitational binding energy W and the instability parameter β are defined as [7]:

$$M_0 \equiv \int d^3x D\,, \tag{8}$$

$$M \equiv \int d^3x(-2T_0^0 + T_\mu^\mu)\alpha\sqrt{\gamma}\,, \tag{9}$$

$$E_{\text{int}} \equiv \int d^3x D\varepsilon\,, \tag{10}$$

$$J \equiv \int d^3x\, T_\phi^0 \alpha\sqrt{\gamma}\,, \tag{11}$$

$$T \equiv \int d^3x \Omega T_\phi^0 \alpha\sqrt{\gamma}\,, \tag{12}$$

$$W \equiv T + E_{int} + M_0 - M\,, \tag{13}$$

$$\beta \equiv T/|W|\,, \tag{14}$$

where $\alpha\sqrt{\gamma}$ is the square root of the four-dimensional metric determinant. Notice that the definitions of quantities such as J, T, W and β are meaningful only in the case of stationary axisymmetric configurations and should therefore be treated with care once the rotational symmetry is lost. All the equilibrium models considered here have been calculated using the relativistic polytropic EOS given in Eq. (3), and we have chosen the polytropic EOS parameters to be $\Gamma = 2.0$, 2.25, 2.5, 2.75, and 3.0 for the adiabatic index, and $K = 165$, 800, 4000, 30000, and 80000 [CU] for the polytropic constant respectively. This choice allows, for each pair of Γ and K, a maximum neutron star mass of $\simeq 2.1 M_\odot$. The exception is $\Gamma = 2.75$, where simulation data from [11], which allows for higher masses, were re-used to save computation time, given their identical numerical setup. Note that these values are different from the ones used in [17] ($\Gamma = 2.0, K = 100$ [CU]). Note, however, that the choice of K does not change the results presented in this work. The actual value of the polytropic constant K fixes the overall scale of the physical system; i.e. the assertion that we are generating and simulating a model with a given baryonic mass M_0 is related to the value chosen for K. Indeed, in order to claim that the threshold for the instability depends on the stiffness of the EOS, we need to eliminate the dependencies on the dimensional scales as well as on the chosen value of the polytropic constant K. An efficient way to do so is to extrapolate the result for $M_0 \to 0$, which corresponds to the Newtonian limit, where the general relativistic effects can be neglected. Using the same procedure followed in [17], we choose sequences of constant rest-mass density models among the following possible values for the total Baryon mass M_0 (0.5, 1.0, 1.5, 2.0, and 2.5 $M_\odot$). We restrict the values of the instability parameter β to the range $[0.255, 0.272]$, and we leave the analysis of models with lower values to future work. The initial conditions for the evolution have been generated using Nicholas Stergioulas' RNS code [26]. Any model can be uniquely determined by three parameters (once the value of the dif-

ferential rotation parameter has been fixed to $\hat{A} = 1$). We have decided to denote each of the generated models using the values of the adiabatic index Γ, the conserved baryonic mass M_0, and the β parameter at $t = 0$. As a consequence of this choice, in the rest of this paper we will refer to a particular model using the following notation. For example, G2.00M1.5b0.270 will denote a model with an adiabatic index of 2.0, a conserved baryonic mass $M_0 = 1.5 M_\odot$ and a value of the initial instability parameter $\beta = 0.270$.

One of the main features of the generated models is that, due to the high rotation, none of them have the density maximum at the center of the star, but rather at some distance from it. This means that all of the models studied are characterized by a *toroidal* configuration, i.e. the maximum of the density is not on the rotational axis. As has been shown in [11], there is not always a correlation between having a toroidal configuration and being unstable against the dynamical bar-mode instability.

B. Numerical setup and evolution method

We use exactly the same numerical setup as in [11]. Because of this, we only briefly describe the specific methods used for this work together with the chosen, relevant, parameters. The reader is referred to [27] for a description of the Einstein Toolkit, and to [11] for details about our particular setup.

The core of the code used for this work is the Einstein Toolkit [27, 28], which is a free, publicly available, community-driven general relativistic (GR) code, capable of performing numerical relativity simulations that include realistic physical treatments of matter, electromagnetic fields [29], and gravity.

The Einstein Toolkit is built upon several open-source components that are widely used throughout the numerical relativity community. Only the ones which were actually used in this work are mentioned below. Many components of the Einstein Toolkit use the `Cactus` Computational Toolkit [30–32], a software framework for high-performance computing (HPC).

Within this study, the adaptive mesh refinement (AMR) methods implemented by `Carpet` [33–35] have been used. Hydrodynamic evolution techniques are provided by the `GRHydro` package [36, 37].

The evolution of the spacetime metric in the Einstein Toolkit is handled by the `McLachlan` package [38]. This code is auto-generated by Mathematica using `Kranc` [39–41], implementing the Einstein equations via a $3 + 1-$dimensional split using the BSSN formalism [42–46].

Within this paper a fourth-order Runge-Kutta [47, 48] method was used, and Kreiss-Oliger dissipation was applied to the curvature evolution quantities in order to damp high-frequency noise.

We use fourth-order finite difference stencils for the curvature evolution, $1 + \log$ [46] slicing, and a Γ-driver shift condition [46]. During time evolution, a
FIG. 2. Snapshots of the rest-mass density ρ in the (x, y) plane for model G2.25M1.5b0.266 at different stages of the evolution, namely $t = 12$ and 18 ms (top row), $t = 24$ and 30 ms (bottom row). The color code is defined in terms of g/cm^3. Additionally, isodensity contours are shown for $\rho = 10^{10}$, 10^{11}, 10^{12}, 10^{13} and 10^{14} g/cm^3.

Sommerfeld-type radiative boundary condition is applied to all components of the evolved BSSN variables as described in [45].

All presented results use the Marquina Riemann solver [49, 50] and PPM (the piecewise parabolic reconstruction method) [51]. An artificial low-density atmosphere with $\rho_{\mathrm{atm}} = 10^{-10}$ [CU] is used, with a threshold of $\rho_{\mathrm{atm\_reset}} = 10^{-7}$ [CU] below which regions are set to be atmosphere. Hydrodynamical quantities are also set to be atmosphere at the outer boundary.

All evolutions presented use a mirror symmetry across the (x, y) plane, consistent with the symmetry of the problem, which reduces the computational cost by a factor of 2. Since we are not interested in investigating whether odd modes play any role, we present only results obtained by imposing an additional π-symmetry, reducing the computational cost by another factor of 2.

III. RESULTS

As discussed in Sec. I and II, the goal of the present work is to study the matter instability that may develop in the case of rapidly differentially rotating relativistic star models, using different configurations of EOSs. The other important requirement we need to fulfill is that our study has to be computationally feasible. To achieve this goal, we need to evolve the largest number of models using the available amount of computational resources in the most efficient way. In selecting a numerical setting we can play with many parameters, namely: the location of the outer boundary, the number of refinement levels, the size and resolution of the finest grid and the symmetries to be imposed on the dynamics. All the simulations in the present work are performed using the same setting for the computational domain. More precisely, we use the same setup as in [11]: three box-in-box (covering the
FIG. 3. Mode dynamics for selected models that are characterized by a value of the instability parameter β between 0.255 and 0.272. Almost all models with $\beta \geq 0.255$ show the typical dynamics one would expect for the dynamical $m = 2$ bar mode instability. The exceptions are models G2.25M0.5b0.255 and G2.25M1.0b0.255, which are not well above β_c. The time interval we used for the fit is reported using a green, shaded area.

quarter space with $x \geq 0$ and $z \geq 0$) refinement levels, with boundaries at distances of $L = 42, 84, 168$ [CU] from the origin of the coordinate system and grid spacings $dx, 2\,dx, 4\,dx$, respectively, where we set $dx = 0.5$ [CU] (that correspond to a resolution $dx \simeq 0.738$ km). Using mirror symmetry across the $x - y$ plane and π symmetry across the $y - z$ plane, this corresponds to a hierarchy of three computational grids, each one of size $85 \times 169 \times 85$ points plus ghost and buffer zones.

We have chosen to use this domain (conservative, though large enough to capture the whole global dynamics of a bar-mode instability) in order to exclude any influence of the computational setup on observed differences between models. The actual size of the finest grid and the computational setup is determined by the most demanding models such that the computed, final quantities do not depend on the used resolution. As shown in the resolution study presented in [11], the usage of the couple β_i, τ_i (see section III.B in [11]) leads to an extrapolation of β_c that is not sensible to the resolution (within the errors). The analysis of [11] shows that this is true for an effective resolution R/dx (R is the equatorial radius of the star) in the range of $\simeq 16/0.25 = 64$ to $\simeq 16/0.84 = 19$, and here the models with the smallest radius (the one with $\Gamma = 3.0$) have been analyzed with an effective resolution in the range of $\simeq 21$ to $\simeq 25$.

Fig. 2 shows a few snapshots for the evolution of the rest-mass density ρ at different times for a representative model, namely G2.25M1.5b0.266 which is characterized by $\Gamma = 2.25$, $\beta = 0.266$ and $M_0 = 1.5\,M_\odot$. This is indeed the typical evolution one would expect for a stellar model which is unstable against the dynamical bar-mode instability.

A. Analysis Methods

In order to compute the growth time of the instability, τ_2, we use the quadrupole moments of the matter distribution Q^{ij}, computed in terms of the conserved density D as

$$Q^{ij} = \int d^3x\, D\, x^i x^j \ . \tag{15}$$

In particular, we perform a nonlinear least-square fit of Q^{xy} (the star spin axis is aligned in the z-direction), using the trial function

$$Q^{xy}(t) = Q_0^{xy} \mathrm{e}^{\frac{t}{\tau_2}} \cos(2\pi f_2 t + \phi_0)\,. \tag{16}$$

Using this trial function, we can extract the growth time τ_2 and the frequency f_2 for the unstable $m = 2$ modes. We also define the modulus $Q(t)$ as

$$Q \equiv \frac{1}{2}\sqrt{(2Q^{xy})^2 + (Q^{xx} - Q^{yy})^2}\,, \tag{17}$$

and the distortion parameter $\eta(t)$ as

$$\eta \equiv \frac{2Q}{(Q^{xx} + Q^{yy})}\,. \tag{18}$$

Finally, we decompose the rest-mass density into its spatial rotating modes $P_m(t)$

$$P_m \equiv \int \mathrm{d}^3x\, \rho\mathrm{e}^{\mathrm{i}m\phi} \tag{19}$$

and the "amplitude" and "phase" of the m-th mode are defined as

$$A_m = |P_m| \quad \text{and} \quad \phi_m \equiv arg(P_m)\,. \tag{20}$$

Despite their name, the amplitudes defined in Eq. (20) do not correspond to proper oscillation eigenmodes of the star but to global characteristics that are selected in terms of their spatial azimuthal shape. Eqs. (16)-(20) are expressed in terms of the coordinate time t, and therefore they are not gauge-invariant. However, the length scale of variation of the lapse function at any given time is always small when compared to the stellar radius, ensuring that events close in coordinate time are also close in proper time.

B. General features of the evolution above the threshold for the onset of the bar-mode instability

The general features of the evolution are common to all the models that show the expected dynamics in presence of the bar-mode $m = 2$ instability. In Fig. 3 the "mode-dynamics" of most of the studied models with $\Gamma = 2.25$ are shown as an example. For all these models (except for G2.25M0.5b0.255 and G2.25M1.0b0.255) it is indeed possible to extract the main features of the $m = 2$ mode using the trial function detailed in Eq. (16). As in [11], we decided to quantify the properties of the bar-mode instability by means of a non-linear fit, using the trial dependence of Eq. (16) on a time interval where the distortion parameter η defined in Eq. (18) is between 1% and 30% of its maximum value.

The results of all these fits are collected in Tab. III in the Appendix, where we report for each model the maximum value assumed by the distortion parameter $\max(\eta)$, the time interval $[t_i, t_f]$ selected for the fit, the value $\beta_i = \beta(t_i)$ corresponding to the value of the instability parameter β at the beginning of the fit interval and τ_2 and f_2, the growth time and frequency that characterize the $m = 2$ bar-mode instability, respectively.

C. Effects of the compactness on the threshold for the onset of the bar-mode instability

We have chosen to investigate the effect of the compactness on the classical bar-mode instability, following the same procedure as in [11, 17], but now for five stiffness values. We determined the critical value of the instability parameter β for the onset of the instability by simulating, for each value of the stiffness, five sequences of initial models having the same value of M_0 but different values of β. For these simulations we decided to

Γ	$M[M_\odot]$	β_c	$A\ [1/\text{ms}^2]$

employ the same resolution $dx = 0.5$ on the finest grid for all cases. This choice was motivated by the need to limit the computational cost.

We now restrict our analysis to the models for which we observed the maximum value of the distortion parameter η to be greater than 0.20 (see Tab. III). For these models, we explicitly checked that the reported unstable modes correspond to the classical bar-mode instability and not to a shear-instability by ensuring that the frequency of the mode divided by two is at most only marginally inside of the co-rotation band of the model.

We have performed a fit for the growth time τ_2 of the bar mode as a function of the instability parameter β for twenty-one sequences of models with constant rest-mass ranging from 0.5 $M_\odot$ to 2.5 $M_\odot$, as shown in Fig. 4. We estimate the threshold for the onset of the instability using the extrapolation technique used in [11, 17] where we assume, in analogy with what expected in the Newtonian case, that the dependence of the frequency of the mode on β is of the type

$$\sigma(\beta) = \Omega(\beta) \pm \sqrt{F(\beta)}, \tag{21}$$

where

$$F(\beta) = \frac{-1}{(\tau_2(\beta))^2} \simeq A(\beta_c - \beta). \tag{22}$$

Results using different polytropic exponents Γ cannot be directly compared to each other to infer the effects of considering a stiffer EOS. The issue is that when considering a polytropic EOS, one can change the units of measurement in such a way that the value of the polytropic constant K is 1. This means that by changing

this value one effectively changes the mass scale and, in turn, the mass of the stellar model considered . Indeed, the assertion that for a star with mass $M_0 = 1.0 M_\odot$ the threshold for the onset of the bar-mode instability is reduced to 0.2498(2) for $\Gamma = 2.75$ from the higher value of 0.25871(9) for $\Gamma = 2.0$ is susceptible to the choice of the mass scale determined by the choice of the values of the polytropic constants. The dependence on the choice of the mass scale can be eliminated by going to the zero-mass limit that corresponds to performing an extrapolation to the *Newtonian* limit of the results. This can be achieved by a linear fit of the reported values for the critical β_c for the onset of the classical bar-mode instability in Tab. (I) as a function of the baryonic rest-mass (see Fig. 4). The result for this fit leads to the following expression for the critical β_c as a function of the the total baryonic mass M_0:

$$\beta_c(M) = \beta_c^N - q \cdot M_0, \tag{23}$$

with different values of the constant depending on the adiabatic index Γ. These values are reported in Tab. II and shown on the bottom right box of Figure 4.

The extrapolated values for β_c in the limit of zero baryonic mass for the relativistic stellar models then lead to a dependency on the compactness of the star alone, expressed as dependency on Γ, shown in Figure 5. As can be seen there, the dependency of β_c on Γ is, within errors, linear in the range $[2.25, 3.0]$, while lower values of Γ deviate notably. We also show results from [17], using $\Gamma = 2.0$ (and $K = 100$), which show a similar deviation. The fact that the case of $\Gamma = 2.0$ is special is not a surprise since in the Newtonian limit, i.e., for small values of central density the equilibrium configuration (see [52]) of a non-rotational polytrope are described by the Lane-Emden equation, and the radius of the Star R and its total mass M are related to the central density ρ_c as $R \propto \rho_c^{(\Gamma-2)/2}$ and $M \propto \rho_c^{(3\Gamma-4)/2}$. That means that the two values $\Gamma = 4/3$ and 2 are very special and represent the transition points to different behavior of the properties of the associated stellar models. In fact, for $\Gamma < 4/3$ we see that the mass decreases for increasing central density, and the models can not be stable, while $\Gamma = 2$ marks a transition point in the relation between the radius of the star and the central density.

Our results show that the dependency of the threshold for the onset of the dynamical bar-mode instability on
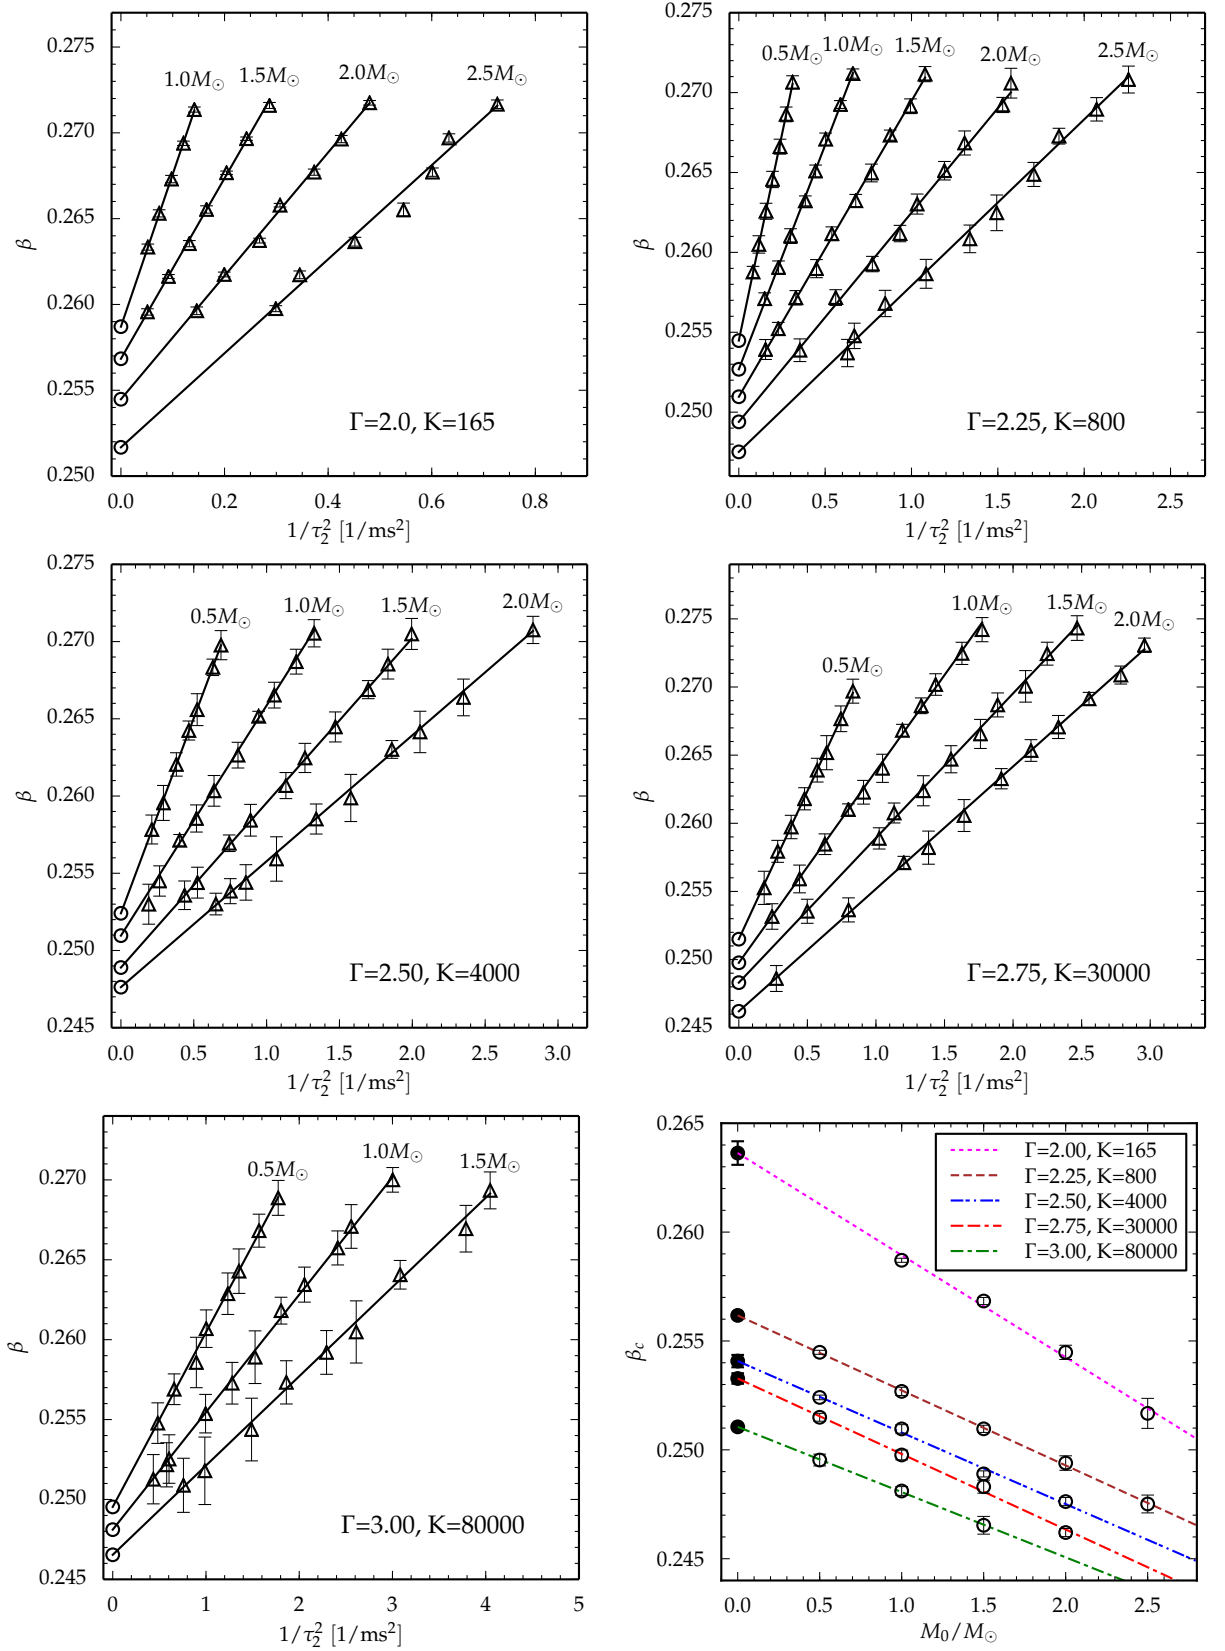

FIG. 4. For each value of the adiabatic index Γ: the critical diagram relating the growth time τ_2 of each unstable model to the value of the instability parameter β. Triangles represent the values corresponding to all the models listed in Tab. III. Specifically, we show the dependency of β at the beginning of the time interval chosen for performing the fit of the $m = 2$ mode growth (reported in Tab. III as $\beta_i = \beta(t_i)$), on $1/\tau_2^2$, in order to highlight the quality of the fit. For all constant rest-mass sequences considered, we also report, with open circles, the extrapolated values β_c, which are used in the bottom right plot to show their dependency on the constant rest-mass, as well as the linear fit to the zero mass limit using Eq. (23).

FIG. 5. Dependency of the threshold β_c^N of the bar-mode instability in the Newtonian limit of zero rest-mass on the stiffness of the EOS, i.e. on Γ, the exponent in the polytropic EOS. An approximate linear trend is visible in the range $2.25 \lesssim \Gamma \lesssim 3.0$, where the linear fit ($\beta_c^N \approx 0.2718 - 0.0069 \cdot \Gamma$) is shown as a black, solid line. The value for the case of $\Gamma = 2.0$ (consistent with the reported results of [17]) does not follow this trend (see discussion in Sec. III C).

Γ is not as large as the previously published results for $\Gamma = 2.0$ [17] and $\Gamma = 2.75$ [11] alone suggested, at least not close to the interesting value of $\Gamma = 2.75$. Further investigation is necessary to clarify the exact dependency at values of Γ lower than 2.25.

IV. CONCLUSIONS

We have presented a study of the dynamical bar-mode instability in differentially rotating NSs in full General Relativity for a wide and systematic range of values of the rotational parameter β and the conserved baryonic mass M_0, using a polytropic/ideal-fluid EOS characterized by a range of values of the adiabatic index $\Gamma = 2.0, 2.25, 2.5, 2.75,$ and 3.0. In particular, we have evolved a large number of NS models belonging to twenty-one different sequences with a constant rest-mass ranging from 0.5 to 2.5 $M_\odot$, with a fixed degree of differential rotation ($\hat{A} = 1$), and with many different values of β in the range $[0.255, 0.278]$.

For all models with a sufficiently high initial value of β we observe the expected exponential growth of the $m = 2$ mode which is characteristic of the development of the dynamical bar-mode instability. We compute the growth time τ_2 for each of these bar-mode unstable models by performing a nonlinear least-square fit using a trial function for the quadrupole moment of the matter dis-

tribution. The growth time clearly depends on both the rest-mass and the rotation and in particular we find, in agreement with previous studies [11, 17], that the relation between the instability parameter β and the inverse square of τ_2, for each sequence of constant rest-mass, is linear. This allows us to extrapolate the threshold value, β_c, for the onset of the instability for each sequence characterized by a fixed value of the baryonic mass (M_0) and of the adiabatic index (Γ), obtaining the results reported in Table I. To show in a scale-independent way how the threshold for the onset of the instability is affected by the change of the adiabatic index Γ, we extrapolated to zero baryonic mass, using the same procedure already employed in [11, 17], to the obtain the critical value β_c^N for each value of Γ (see Table II and Figure 5). It can be seen there is a sensible stiffness effect on the dynamics of the bar-mode instability. In detail, we find that the critical value for the onset of the instability decreases with increasing stiffness (Γ) of the EOS, and that this effect is greater in the range of $\Gamma = 2$ to $\Gamma = 2.25$ than for higher values of Γ (< 3.0). In particular, we find a mild linear dependency (see Fig. 5) of β_c^N on Γ, within errors, in the the range $2.25 \lesssim \Gamma \lesssim 3.0$.

We conclude that, for an astrophysical interesting value of $\Gamma \simeq 2.75$, the dependence of the critical value of β for the onset of bar-mode instability is considerably smaller than suggested by previously published results for $\Gamma = 2.0$ [17] and $\Gamma = 2.75$ [11] alone.

Appendix: Fit results

Here we collect the results of all fits mentioned in Sec. III B, together with Figure 6, which shows the dynamics of most of the models for Γs different from the one in Figure 3. We also report in Tab. III for each model the maximum value assumed by the distortion parameter $\max(\eta)$, the time interval $[t_i, t_f]$ selected for the fit, the value $\beta_i = \beta(t_i)$ corresponding to the value of the instability parameter β at the beginning of the fit interval and τ_2 and f_2, the growth time and frequency that characterize the $m = 2$ bar-mode instability, respectively.

TABLE III: Results for various quantities for all models, sorted by value of Γ, mass and β. We report for each model the maximum value assumed by the distortion parameter max(η), the time interval $[t_i, t_f]$ selected for the fit, the value $\beta(t_i)$ corresponding to the value of the instability parameter β at the beginning of the fit interval and τ_2 and f_2, the growth time and frequency that characterize the $m = 2$ bar-mode instability, respectively.
