May 9, 2016

**Abstract:** The observability of a gluino at LHC RUN II is analyzed for the case where the gluino lies in the gluino-neutralino coannihilation region and the mass gap between the gluino and the neutralino is small. The analysis is carried out under the Higgs boson mass constraint and the constraint of dark matter relic density consistent with the WMAP and Planck experiment. It is shown that in this case a gluino with mass much smaller than the current lower limit of  $\sim 1500$  GeV as given by LHC RUN II at  $3.2 \text{ fb}^{-1}$  of integrated luminosity would have escaped detection. The analysis is done using the signal regions used by the ATLAS Collaboration where an optimization of signal regions was carried out to determine the best regions for gluino discovery in the gluino-neutralino coannihilation region. It is shown that under the Higgs boson mass constraint and the relic density constraint, a gluino mass of  $\sim 700$  GeV would require  $14 \text{ fb}^{-1}$  of integrated luminosity for discovery and a gluino of mass  $\sim 1250$  GeV would require  $3400 \text{ fb}^{-1}$  of integrated luminosity for discovery at LHC RUN II. An analysis of dark matter for this case is also given. It is found that for the range of gluino masses considered, the neutralino mass lies within less than 100 GeV of the gluino mass. Thus a measurement of the gluino mass in the gluino-neutralino coannihilation region will provide a determination of the neutralino mass. In this region the neutralino is dominantly a gaugino and the spin-independent proton-neutralino cross section is small but much larger than the neutrino floor lying in the range  $\sim (1 - 10) \times 10^{-47} \text{ cm}^2$ . Thus a significant part of the parameter space of the model will lie within the reach of the next generation LUX-ZEPLIN dark matter experiment.

## 1 Introduction

The fact that sparticles have not been observed so far appears to imply that the scale of weak scale supersymmetry (SUSY) is higher than previously thought, lying in the several TeV region. This reasoning receives support from the observation that the Higgs boson [1–3] mass measurements give a mass of  $\sim 126$  GeV, [4, 5] while in supersymmetry the tree-level Higgs boson mass must lie below the mass of the Z boson. Thus the extra mass must arise from loop corrections, which then requires that the SUSY scale be in the several-TeV region [6, 7]. However, softly broken supersymmetry has more than one mass scale and a look at the loop correction indicates that the SUSY scale that enters is the third generation mass. Specifically, the gaugino masses are largely unconstrained and

---

\*Email:p.nath@neu.edu

†Email:a.spisak@neu.edu

their scale could be much lower, allowing their early discovery. On the other hand, LHC data also appears to put significantly high limits, i.e. above 1.5 TeV, for the gluino mass [8].

In this work we show that in the gluino-neutralino coannihilation region, gluino masses lower than 1 TeV would have escaped detection at LHC RUN I and also in the analyses at LHC RUN II based on the accumulated integrated luminosity of  $3.2 \text{ fb}^{-1}$ . [8]. Specifically we carry out an analysis in the framework of a high-scale supergravity grand unified model [9] with radiative breaking of the electroweak symmetry (for a reviews see [10]). The supergravity unified models admit a large landscape for sparticle masses [11] which allows for low mass gluinos [11–14] and specifically sparticle landscapes where the gluino is the next-to-lightest supersymmetric particle (NLSP). The largeness of the sparticle landscape arises due the fact that one may have non-universal supergravity models [15–17].

We investigate the sparticle spectrum in the gluino-neutralino coannihilation region under the Higgs boson mass constraints and the relic density constraint. In these models the universal scalar mass is taken to be high, lying in the several TeV region, but with low-lying gluino masses. Models we consider allow for radiative breaking of the electroweak symmetry and lie on the hyperbolic branch, [18] where large scalar masses can arise with low fine tuning. A number of works have analyzed these SUGRA models [19–25].

Here we consider the possibility that if the first and second generation GUT scale gaugino masses  $m_1 = m_2$  are high while the third-generation gaugino mass  $m_3$  is low, there can exist light gluinos with masses close to the LSP mass that have evaded detection at the LHC so far, and may yet be discoverable at LHC RUN II. Coannihilation of a light gluino with mass near the LSP neutralino provides a mechanism for achieving a dark matter relic density consistent with experimental constraints from WMAP [26] and Planck [27]. The analysis shows that in the gluino-neutralino coannihilation region, gluino masses in the range 700–1300 GeV exist consistent with Higgs boson mass constraint and relic density constraint and would have escaped detection so far, but would be accessible at LHC RUN II with up to  $3000 \text{ fb}^{-1}$  of integrated luminosity. A search for signal regions for the discovery of the gluino in the gluino-neutralino coannihilation region was carried out. For each model point seven signal regions as listed by the ATLAS Collaboration [8] and displayed in table 1 were analyzed. In this table,  $H_T$  is defined as the scalar sum of the transverse momentum of all jets,  $M_{\text{eff}}(\text{incl.})$  is defined as the scalar sum of  $E_T^{\text{miss}}$  and the transverse momentum of all jets with  $p_T > 50 \text{ GeV}$ , while  $M_{\text{eff}}(N_j)$  is the scalar sum of  $E_T^{\text{miss}}$  and the transverse momentum of the first  $N$  jets. Each signal region is defined by up to 12 different cuts which are on jet  $P_T$ 's,  $E_T^{\text{miss}}$ , etc., which are meant to reduce the background and enhance the signal. It is found that over the entire gluino mass region analyzed, the optimum signal regions are  $2jl$  and  $2jm$  (using the nomenclature of ATLAS [8]) where  $2jl$  and  $2jm$  are as defined in table 1.

The outline of the rest of the paper is as follows: In section 2 we examine the parameter space of models with coannihilation of a light ( $< 2 \text{ TeV}$ ) gluino with the LSP under the constraints of the Higgs boson mass, WMAP and Planck relic density, and LHC RUN I exclusions on the sparticle mass spectra. In section 3 we carry out a signature analysis of a subset of benchmark model points for LHC RUN II. For these we analyze the seven signal regions of table 1 and determine the leading and the subleading signal regions and the minimum integrated luminosity for LHC discovery for each of the model points analyzed. This allows us to determine the range of gluino masses which would have escaped detection thus far but would be accessible at LHC RUN II with up to  $3000 \text{ fb}^{-1}$  of integrated luminosity. We also compare to the latest constraints from ATLAS [8] using simplified models with  $3.2 \text{ fb}^{-1}$  of integrated luminosity for the 13 TeV data. In section 3.3 we carryout a signal region optimization. In section 4 we investigate the direct detection of dark matter for the

benchmark points of section 3. Conclusions are given in section 5.

## 2 Parameter Space for Gluino Coannihilation in Non-Universal SUGRA

As mentioned in section 1, non-universal supergravity models allow for the possibility of non-universalities in the gaugino masses. In this work we consider this possibility by assuming that the scalar masses are all universal at high scale but the gaugino masses are split, i.e., gaugino masses in the  $U(1)$  and  $SU(2)$  sectors are equal, while the  $SU(3)_C$  gaugino mass is not. Specifically we assume the following parameter space for the model:

$$m_0, A_0, m_1 = m_2 \neq m_3, \tan\beta, \text{sgn}(\mu) \quad (1)$$

where  $m_0$  is the universal scalar mass,  $m_1 = m_2$ , where  $m_1, m_2$  are the gaugino masses for the  $U(1)$  and  $SU(2)$  sectors and  $m_3$  is the  $SU(3)_C$  gaugino mass,  $A_0$  is the universal trilinear scalar coupling (all at the grand unification scale) and  $\tan\beta = \langle H_2 \rangle / \langle H_1 \rangle$ , where  $H_2$  gives mass to the up quarks and  $H_1$  gives mass to the down quarks and the leptons, and  $\text{sgn}(\mu)$  is the sign of the Higgs mixing parameter which enters in the superpotential in the term  $\mu H_1 H_2$ . Using the above parameter space the sparticle spectrum is generated using `SoftSusy 3.5.1` [28] while the analysis of the relic density is done using `Micromegas 4.1.7` [29] and SLHA-format data files are processed using `PySLHA` [30].

We wish to examine the region of gluino-neutralino coannihilation which requires that the gluino be the next-to-lightest supersymmetric particle (NLSP). In high scale models this can be achieved by letting  $m_3$  lie significantly lower than the common scale  $m_1 = m_2$ , as shown in table 2. Thus in table 2 we list several models which are chosen as illustrative examples. In generating the parameter set of table 2 we have imposed the constraints that the Higgs boson mass obey  $m_h = 125 \pm 2$  GeV and  $\Omega h^2 = 0.11 \pm 0.013$  consistent with WMAP and Planck experiments. The ranges are chosen to take account of possible errors in theoretical computations given by codes.

Table 2 shows that the gluino mass lies close to the neutralino mass with their mass difference lying in the range of  $\sim (70 - 100)$  GeV and the gluino mass being around  $1.1 \times$  the neutralino mass over essentially the entire gluino mass range. It is also to be noted that the scale of  $m_0$  is high, lying in the several TeV region, while the light stop mass lies in the range between 2-3 TeV. The largeness of the third generation scalar masses is what provides a large loop correction to the Higgs boson to lift its tree value to the desired experimentally-observed value. The reason for the selection of the illustrative models of table 2 as noted earlier is the following: As discussed in section 3 all of the models in table 2 would have escaped detection at LHC RUN I but would be observable at LHC RUN II.

## 3 Signal Analysis for Gluino-Neutralino Coannihilation Models at LHC RUN-II

After applying the Higgs boson and the relic density constraints to the gluino-neutralino coannihilation region, a set of benchmark points was selected for a Monte Carlo analysis of LHC signal regions (see table 2). This analysis was performed with the `MadGraph 2.2.2` [31] software system.

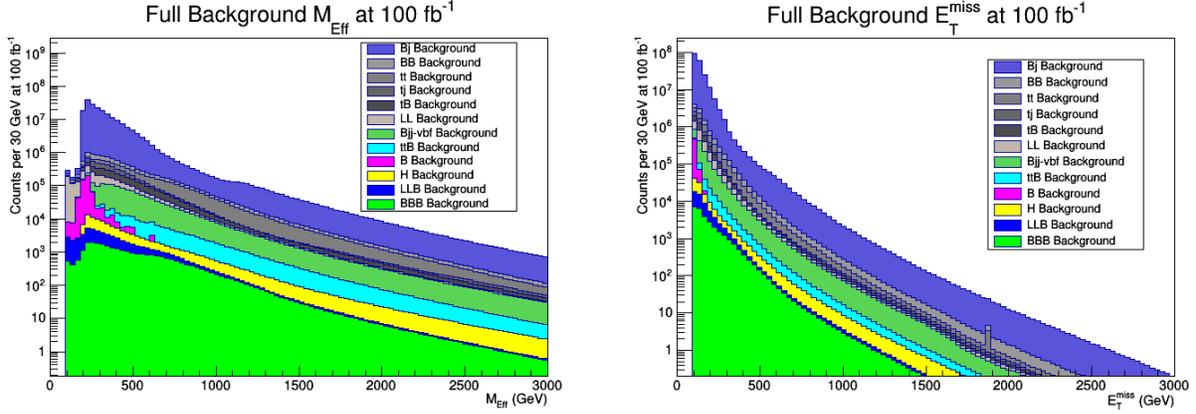

Figure 1: A display of Standard Model SNOWMASS background after triggering cuts and a  $E_T^{\text{miss}} \geq 100$  GeV pre-cut. The background is broken into individual processes with the y-axis displaying the number of events per 30 GeV scaled to an integrated luminosity of  $100 \text{ fb}^{-1}$  at LHC RUN II. The left panel displays the distribution as a function of  $M_{\text{Eff}}(\text{incl.})$  while the right panel displays the distribution as a function of  $E_T^{\text{miss}}$ . Individual background processes are colored according to eq. (3).

First, the Feynman diagrams were calculated for all possible decays of the form  $p p \rightarrow \text{SUSY SUSY}$ , where ‘‘SUSY’’ can be any MSSM particle. The analysis is configured to include both ISR and FSR jets. With the sparticle spectra of the benchmark points calculated by `SoftSUSY`, as well as the decay widths and branching ratios calculated by `SDECAY` [32, 33] and `HDECAY` [34, 35] operating within `SUSY-HIT 1.5` [36], `MadEvent` was used to simulate 50,000 MSSM decay events for each benchmark point. Hadronization of resultant particles is handled by `Pythia 6.4.28` [37], and ATLAS detector simulation and event reconstruction is performed by `Delphes 3.1.2` [38]. A large set of search analyses were performed on the generated events for each benchmark point. The analyses used `ROOT 5.34.21` [39] to implement search region details for the recently published 2-6 jet plus missing transverse energy signal search regions at 13 TeV [8], which look specifically for light squarks and gluons.

To allow comparison to the background, all of the signal region analyses were applied to pre-generated backgrounds published by the SNOWMASS group [40]. For each benchmark point, a calculated implied luminosity allowed direct comparison to the backgrounds. Each individual background process from the SNOWMASS background set was scaled by its own implied luminosity and combined to determine a total background count for each signal region. Fig. 1 displays distributions in two key kinematic quantities,  $M_{\text{eff}}$  and  $E_T^{\text{miss}}$ , for individual processes and their relative contribution to the overall background after minimal cuts for trigger simulation and a  $E_T^{\text{miss}} \geq 100$  GeV pre-cut, but before any specific cuts for signal regions. Here and throughout,  $M_{\text{eff}}$  is specifically  $M_{\text{eff}}(\text{incl.})$ , defined as the scalar sum of  $E_T^{\text{miss}}$  and the  $p_T$  of all jets with  $p_T(j) \geq 50$  GeV. The various background samples are grouped according to the generated final state, with a collective notation given by

$$\begin{aligned}
 J &= \{u, \bar{u}, d, \bar{d}, s, \bar{s}, c, \bar{c}, b, \bar{b}\}, \\
 L &= \{e^+, e^-, \mu^+, \mu^-, \tau^+, \tau^-, \nu_e, \nu_\mu, \nu_\tau\}, \\
 V &= \{W^+, W^-, Z, \gamma, h_0\}, T = \{t, \bar{t}\}, H = \{h_0\}.
 \end{aligned}
 \tag{2}$$

In general, events with gauge bosons and SM Higgs bosons in the final state are grouped into a single “boson” (B) category. Thus, for example, the data set “Bjj-vbf” represents production via vector boson fusion of a gauge boson or a Higgs with at least two additional light-quark jets.

### 3.1 LHC Production and Signal Definitions

The multi-jet search strategy described in [8] defines seven signal regions are defined with jet multiplicities ranging from 2 to 6 jets with cuts on the inclusive effective mass  $M_{\text{eff}}(\text{incl.})$  varying from “loose” (low  $M_{\text{eff}}(\text{incl.})$ ) to “tight” (high  $M_{\text{eff}}(\text{incl.})$ ). When examining the results for the gluino coannihilation benchmark points,  $2jm$  and  $2jl$  were found to be the dominant and subdominant signal regions for discovery.

Requirement	Value						
	2jl	2jm	2jt	4jt	5j	6jm	6jt
$E_T^{\text{miss}} \text{ (GeV)} >$	200	200	200	200	200	200	200
$p_T(j_1) \text{ (GeV)} >$	200	300	200	200	200	200	200
$p_T(j_2) \text{ (GeV)} >$	200	50	200	100	100	100	100
$p_T(j_3) \text{ (GeV)} >$	–	–	–	100	100	100	100
$p_T(j_4) \text{ (GeV)} >$	–	–	–	100	100	100	100
$p_T(j_5) \text{ (GeV)} >$	–	–	–	–	100	100	100
$p_T(j_6) \text{ (GeV)} >$	–	–	–	–	–	100	100
$\Delta\phi(\text{jet}_{1,2,(3),E_T^{\text{miss}}})_{\text{min}} >$	0.8	0.4	0.8	0.4	0.4	0.4	0.4
$\Delta\phi(\text{jet}_{i>3,E_T^{\text{miss}}})_{\text{min}} >$	–	–	–	0.2	0.2	0.2	0.2
$E_T^{\text{miss}}/\sqrt{H_T} \text{ (GeV)}^{1/2} >$	15	15	20	–	–	–	–
$E_T^{\text{miss}}/M_{\text{eff}}(N_j) >$	–	–	–	0.2	0.25	0.25	0.2
$M_{\text{eff}}(\text{incl.}) \text{ (GeV)} >$	1200	1600	2000	2200	1600	1600	2000

Table 1: The selection criteria used for the signal regions in the nomenclature of Table 2 of the ATLAS analysis [8].

Using the techniques and signal regions described above, we analyzed each of the benchmark points of table 2 to identify a signal region of minimum required luminosity for  $5\sigma$  signal/ $\sqrt{\text{background}}$  discovery of this point at the LHC RUN II. These results can be directly compared to the results of [8] for simplified models involving gluinos and neutralinos with decoupled squarks. In that analysis it was found that for such a simplified model, using  $3.2 \text{ fb}^{-1}$  of data on the same signal regions to detect the same gluino decay channel ( $\tilde{g} \rightarrow q\bar{q}\tilde{\chi}_1^0$ ), a gluino mass lower limit of  $\sim 1500 \text{ GeV}$  is established for neutralino masses up to  $\sim 800 \text{ GeV}$ . For LSP masses above this, no exclusion is established at  $3.2 \text{ fb}^{-1}$  for any gluino masses, demonstrating that the gluino-neutralino coannihilation region remains viable for continued searching.

Model	Glucino	Neutralino	Stop	Higgs	$\Omega_{\text{LSP}} h^2$	$m_0$	$A_0$	$m_1 = m_2$	$m_3$

### 3.2 Discussion of results

In table 3 we give an analysis of the SUSY production cross sections, which for the gluino-neutralino coannihilation models considered here is essentially limited to gluino pair production. The main mechanisms for gluino production are gluon fusion  $gg \rightarrow \tilde{g}\tilde{g}$  and  $q\bar{q} \rightarrow \tilde{g}\tilde{g}$ . Because of the small mass gap between the gluino and neutralino masses needed for gluino-neutralino coannihilation, the decay of the gluino is dominated by three-body decay involving a neutralino and quarks, i.e. by the process  $\tilde{g} \rightarrow q\bar{q}\tilde{\chi}_1^0$ . The subleading decay is  $\tilde{g} \rightarrow g\tilde{\chi}_1^0$  which is typically only a few percent with the decay mode  $\tilde{g} \rightarrow q\bar{q}\tilde{\chi}_1^0$  being as as much as 95% or more over most of the parameter space, as can be seen in table 3 by adding the two columns on the right.

Using the signal regions defined in [8], it is found (see table 4 and table 5) that the two leading signal regions for the detection of the decay of the gluino for the gluino-neutralino coannihilation models are  $2jl$  and  $2jm$  over the entire range of gluino masses given in table 2. Specifically, in table 5 we present a grid where the ratio signal/ $\sqrt{\text{background}}$  for each of the Model (i) - (vii) for the seven signal regions is exhibited for an integrated luminosity sufficient for the discovery of the corresponding model. It is seen that for Model (i)  $2jl$  is the discovery signal region while for Models (ii)-(vii),  $2jm$  is the signal region for discovery. All other signal regions lie significantly below the threshold. Since for each signal region up to 12 kinematical variables with cuts are utilized, it is of interest to analyze in further detail as to the most sensitive of these kinematical quantities that allow us to discriminate the signal over the background. It is found that among the twelve kinematical variables, three stand out as the most sensitive for our analysis. These are  $M_{\text{eff}}$ ,  $E_T^{\text{miss}}$ , and  $E_T^{\text{miss}}/\sqrt{H_T}$ . We illustrate this for the cases (i), (ii), (vi), and (vii) below.

For Model (i) the sparticle mass spectrum is exhibited in fig. 2, which shows the mass hierarchy of all the sparticle states. The sparticles lying in the mass region below 2.5 TeV have the mass hierarchy

$$m_{\tilde{\chi}_1^0} < m_{\tilde{g}} < m_{\tilde{\chi}_1^\pm} \simeq m_{\tilde{\chi}_2^0} < m_{\tilde{t}_1} < m_{\tilde{\chi}_2^\pm} \simeq m_{\tilde{\chi}_{3,4}^0} . \quad (3)$$

In the sparticle landscape this is the mass hierarchy labeled NUSP14 in the nomenclature of [12]. This hierarchy is a useful guide to what one may expect in this class of models. In the left panel of fig. 3 we exhibit the  $2jl$  signal region for this model, where we plot the number of SUSY signal

events (red) and the square root of the total standard model background (blue) vs.  $M_{Eff}$ . The analysis is done for LHC RUN II at an integrated luminosity of  $14 \text{ fb}^{-1}$ . Similar analyses are given in the middle panel of fig. 3 for  $E_T^{miss}$  and in the right panel of fig. 3 for  $E_T^{miss}/\sqrt{H_T}$ . Very similar analyses were carried out for Models (ii), (vi), and (vii) in fig. 4, fig. 5, and fig. 6. Here, however, the leading signal region is 2jm and the analyses are done at an integrated luminosity of  $66 \text{ fb}^{-1}$  for Model (ii) in fig. 4, at  $2000 \text{ fb}^{-1}$  for Model (vi) in fig. 5, and at  $3400 \text{ fb}^{-1}$  for Model (vii) in fig. 6. In each of these cases the SUSY signal meets the  $5\sigma$  limit needed for discovery. A tabulation of the integrated luminosity needed for the discovery of all the models of table 2 is given in table 4.

The analysis of fig. 3, fig. 4, fig. 5, fig. 6 and of table 4 shows the remarkable reduction in the potential of LHC RUN II for the discovery of gluino if the gluino mass lies in gluino-neutralino coannihilation region. A further illustration of this result is given in fig. 7 where the largest gluino mass discoverable as a function of the integrated luminosity at LHC RUN II is given if the gluino mass lies in the gluino-neutralino coannihilation region. Specifically one finds that even with  $\sim 3000 \text{ fb}^{-1}$  of integrated luminosity LHC RUN II will probe a gluino mass of  $\sim 1200 \text{ GeV}$  in this case. In contrast away from the gluino-neutralino coannihilation region, the discovery potential of LHC RUN II increases in a dramatic fashion as illustrated by the red dot in the upper left hand corner of fig. 7, which is taken from the ATLAS analysis [8] using  $3.2 \text{ fb}^{-1}$  of integrated luminosity at LHC RUN II. Thus the analysis of fig. 7 shows that if the gluino mass lies in the gluino-neutralino coannihilation region, its mass could be much smaller than the current lower limits, where the mass gap between the gluino mass and the neutralino mass is large.

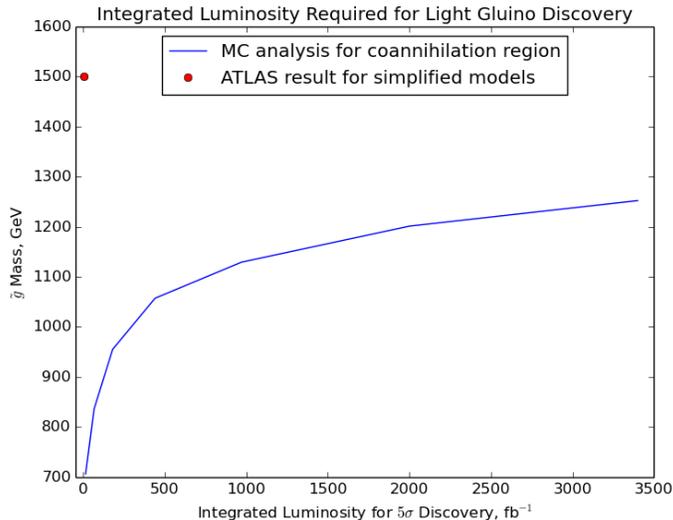

Figure 7: Integrated luminosity required at LHC RUN II for  $5\sigma$  discovery of gluino in the gluino-neutralino coannihilation region as a function of the gluino mass. For comparison ATLAS result from [8] using simplified models is also exhibited. One finds that the exclusion limit for the gluino mass in the coannihilation region is much lower than the ATLAS result.

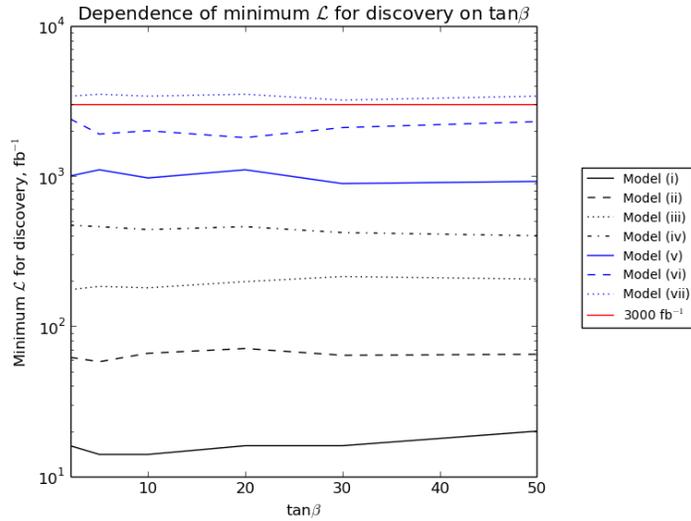

Figure 8: Integrated luminosity required at LHC RUN II for  $5\sigma$  discovery of a gluino in the gluino-neutralino coannihilation as a function of  $\tan\beta$  for each of the Models (i)-(vii). The dependence of the integrated luminosity required for  $5\sigma$  discovery is seen to have only a mild dependence on  $\tan\beta$ .

### 3.3 Signal Region Optimization

Because the signal regions as defined in [8] are for generic simplified model light gluinos, it is advantageous to consider whether the signals can be improved upon by altering cuts to one or several of the variables in table 4. It was found that very modest reduction (between 2 and 10 percent) in integrated luminosity required for  $5\sigma$  discovery can be achieved in the  $2jm$  signal region by altering the cut on the variable  $E_T^{\text{miss}}/\sqrt{H_T}$ . To demonstrate this choice, figure 9 shows the results of the  $2jm$  signal region in Models (i), (ii), (vi), and (vii) prior to any cuts on  $E_T^{\text{miss}}/\sqrt{H_T}$ , at the required integrated luminosity for discovery for that model.

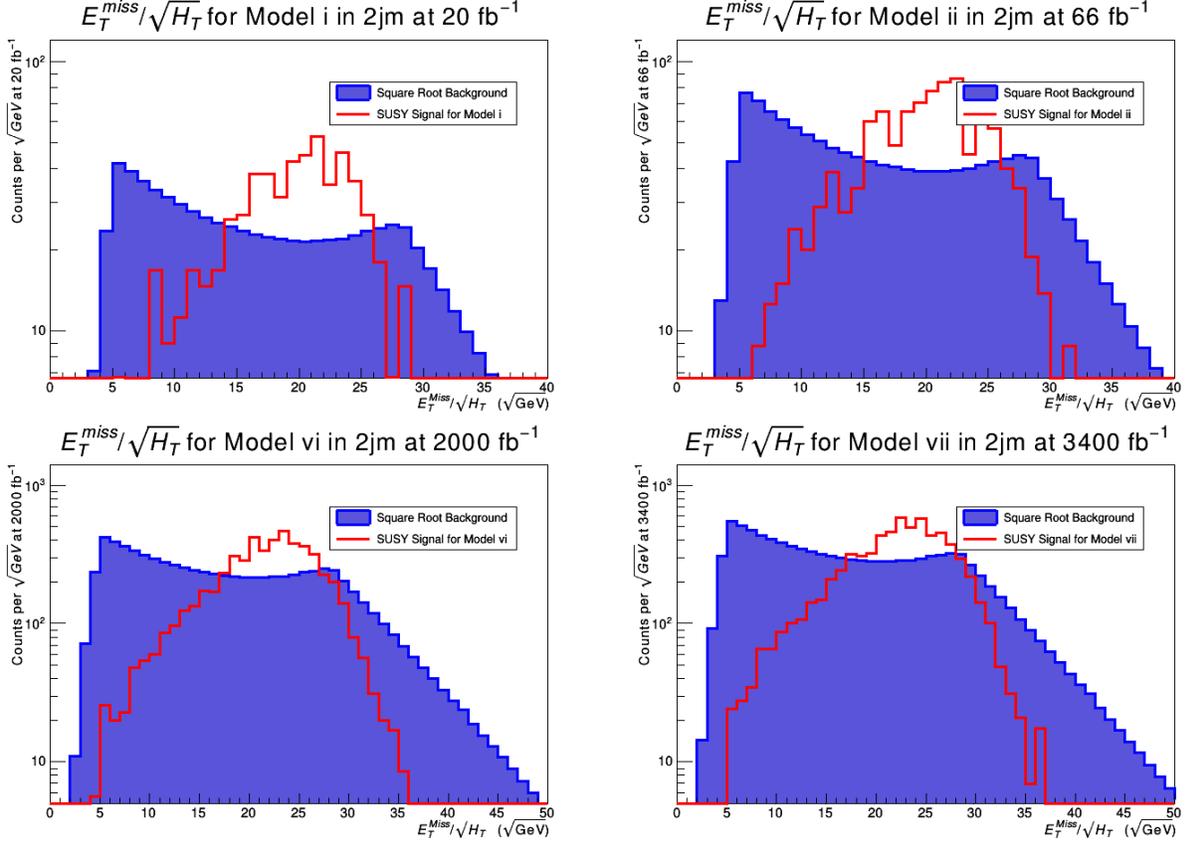

Figure 9: Upper Left panel: Distribution in  $E_T^{miss}/\sqrt{H_T}$  for the  $2jm$  signal region for gluino-neutralino coannihilation Model (i) prior to any cuts in  $E_T^{miss}/\sqrt{H_T}$ . The analysis is done at  $20 \text{ fb}^{-1}$  of integrated luminosity at the energy scale of LHC RUN II, which gives a  $5\sigma$  discovery in this signal region. Upper Right Panel: The same analysis but for Model (ii) at  $66 \text{ fb}^{-1}$  of integrated luminosity. Lower Left Panel: The same analysis but for Model (vi) at  $2000 \text{ fb}^{-1}$  of integrated luminosity. Lower Right Panel: The same analysis but for Model (vii) at  $3400 \text{ fb}^{-1}$  of integrated luminosity.

By analyzing these figures, the original choice to require  $E_T^{miss}/\sqrt{H_T} > 15\sqrt{\text{GeV}}$  (see table 1) is shown to be a very good choice, as this is the point where the SUSY signal (in red) overtakes the square root of the SM background (in blue). However, some improvement can be made by also requiring  $E_T^{miss}/\sqrt{H_T}$  to be less than a specific critical value, where the SUSY signal drops below the square root of the SM background. This occurs around the value of  $25 \sqrt{\text{GeV}}$  for the lighter models (Model (i) and (ii)) and around  $30 \sqrt{\text{GeV}}$  for the heavier models (Model (vi) and (vii)). For the optimization, a value of  $30 \sqrt{\text{GeV}}$  was chosen to optimize the fit for the heaviest gluino models, thereby extending the reach of the LHC. We call this signal region  $2jm-HT$ . Table 6 indicates the improvement by modifying the cut on  $E_T^{miss}/\sqrt{H_T}$  in this way, while figure 10 displays the binned count data after the optimized cut. Further improvement may be possible by investigating the substructure of the jets themselves, as discussed in [41].

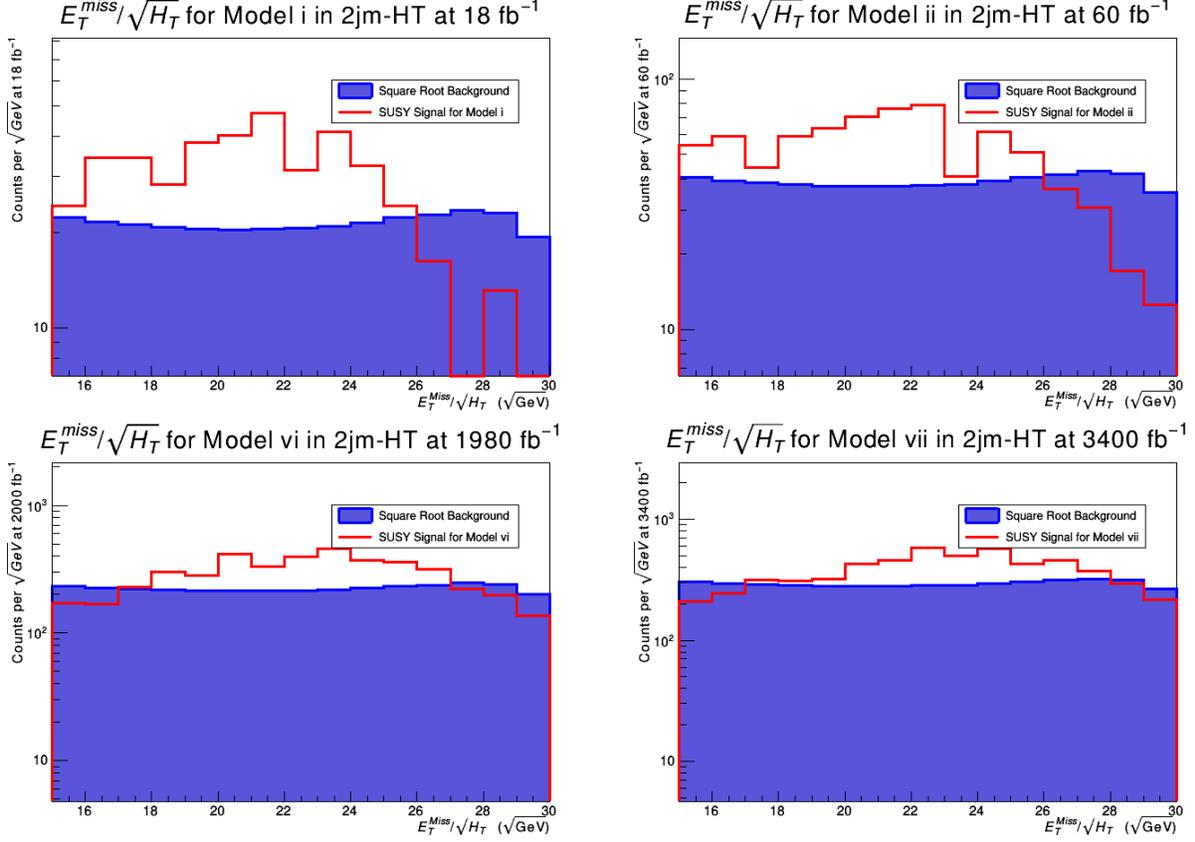

Figure 10: Upper Left panel: Distribution in  $E_T^{\text{miss}}/\sqrt{H_T}$  for the  $2jm - HT$  signal region for gluino-neutralino coannihilation Model (i) after optimized cuts in  $E_T^{\text{miss}}/\sqrt{H_T}$ . The analysis is done at  $18 \text{ fb}^{-1}$  of integrated luminosity at the energy scale of LHC RUN II, which gives a  $5\sigma$  discovery in this signal region. Upper Right Panel: The same analysis but for Model (ii) at  $60 \text{ fb}^{-1}$  of integrated luminosity. Lower Left Panel: The same analysis but for Model (vi) at  $1980 \text{ fb}^{-1}$  of integrated luminosity. Lower Right Panel: The same analysis but for Model (vii) at  $3400 \text{ fb}^{-1}$  of integrated luminosity.

Model	$\mathcal{L} (\text{fb}^{-1})$ in 2jm	$\mathcal{L} (\text{fb}^{-1})$ in 2jm-HT
(i)	20	18
(ii)	66	60
(iii)	180	170
(iv)	440	420
(v)	970	950
(vi)	2000	1980
(vii)	3400	3400

Table 6: Integrated luminosity for SUSY discovery in  $2jm$  and  $2jm-HT$ , where  $2jm-HT$  requires that  $15 < E_T^{\text{miss}}/\sqrt{H_T} < 30$  in units of  $\sqrt{\text{GeV}}$

## 4 Gluino Coannihilation, LHC and Direct Detection of CDM

We discuss now further details of the gluino-neutralino coannihilation model. For the case when the gluino is the NLSP the processes that enter in coannihilation are

$$\tilde{\chi}^0\tilde{\chi}^0 \rightarrow SM, \tilde{\chi}^0\tilde{g} \rightarrow SM', \tilde{g}\tilde{g} \rightarrow SM'', \quad (4)$$

where  $SM, SM', SM''$  stand for Standard Model states. In the analysis of coannihilation the mass gap between the LSP and the NLSP plays a critical role. Thus in general for processes  $\tilde{\chi}_i\tilde{\chi}_j \rightarrow SM$  the coannihilation is controlled by the ratio  $\delta_i$  [42–44]

$$\delta_i = \frac{n_i^{\text{eq}}}{n^{\text{eq}}} = \frac{g_i(1 + \Delta_i)^{3/2}e^{-\Delta_i x}}{\sum_j g_j(1 + \Delta_j)^{3/2}e^{-\Delta_j x}}, \quad (5)$$

where  $g_i$  are the degrees of freedom of  $\chi_i$ ,  $x = m_1/T$  and  $\Delta_i = (m_i - m_1)/m_1$ , with  $m_1$  defined as the LSP mass and where  $e^{-\Delta_i x}$  is the Boltzmann suppression factor. The relic density involves the integral

$$J_{x_f} = \int_{x_f}^{\infty} x^{-2} \langle \sigma_{\text{eff}} v \rangle dx, \quad (6)$$

where  $v$  is the relative velocity of annihilating supersymmetric particles,  $\langle \sigma_{\text{eff}} v \rangle$  is the thermally averaged cross section times the relative velocity, and  $x_f$  is the freeze out temperature. The  $\sigma_{\text{eff}}$  that enters Eq.(6) has the approximate form

$$\sigma_{\text{eff}} \simeq \sigma_{\tilde{g}\tilde{g}} \delta_{\tilde{\chi}^0}^2 \left( \delta^2 + 2\delta \frac{\sigma_{\tilde{\chi}^0\tilde{g}}}{\sigma_{\tilde{g}\tilde{g}}} + \frac{\sigma_{\tilde{\chi}^0\tilde{\chi}^0}}{\sigma_{\tilde{g}\tilde{g}}} \right), \quad (7)$$

Here  $\delta = \delta_{\tilde{g}}/\delta_{\tilde{\chi}^0}$  and  $\delta_i$  are defined by Eq.(5). Numerical analysis shows that  $\sigma_{eff}$  is dominated by the processes involving the gluino such that a smaller the mass gap between the gluino and the LSP leads to more dominant gluino processes. The relic density depends critically on the mass gap and we wish to keep the relic density constant as the gluino mass increases. However, an increasing gluino mass reduces the cross section for the annihilating gluino. In order to compensate for the reduction in the gluino annihilation cross section so that  $\sigma_{\text{eff}}$  remains constant, the mass gap between the gluino and the LSP must decrease (see the first paper of [14] and [12]). Specifically one requires that

$$\Delta_{\tilde{g}\tilde{\chi}^0} = (m_{\tilde{g}}/m_{\tilde{\chi}^0} - 1) \quad (8)$$

must decrease as the LSP mass increases to achieve constancy of the relic density. This is what is seen in the analysis of table 2. Further, from the trend in table 2 one expects that as the gluino mass gets large  $m_{\tilde{g}}/m_{\tilde{\chi}^0} \rightarrow 1$  and  $\Delta_{\tilde{g}\tilde{\chi}^0} \rightarrow 0$  in order to achieve relic density in the desired range. A similar phenomenon was seen in the analysis of [45].

It is pertinent to ask what the effect of non-perturbative corrections to annihilation cross section implies regarding the relic density analysis. In general, non-perturbative corrections can be significant

near the threshold since here multiple gluon exchanges can occur, which produce the Sommerfeld enhancement factor. These effects may be approximated by the function  $\mathcal{E}$ , [13] where

$$\mathcal{E}_j = \frac{C_j \pi \alpha_s}{\beta} \left[ 1 - \exp \left\{ -\frac{C_j \pi \alpha_s}{\beta} \right\} \right]^{-1}. \quad (9)$$

Here  $C_{j=g(q)} = 1/2(3/2)$  for  $\tilde{g}\tilde{g} \rightarrow gg$  ( $\tilde{g}\tilde{g} \rightarrow q\bar{q}$ ), where  $\beta = \sqrt{1 - 4m_g^2/s}$ . In [12] an analysis was carried out for the relic density including the effect of the Sommerfeld enhancement and results compared to the one using `micrOMEGAs`, which uses only perturbative cross section. The analysis of [12] shows that the effect of Sommerfeld enhancement is equivalent to an upward shift of the gluino mass by 3-6 GeV without the inclusion of the Sommerfeld enhancement. Thus, based on the analysis of [12], inclusion of Sommerfeld enhancement would modify the results by only a few percent and our conclusions are not affected in any significant way.

In addition to the Sommerfeld enhancement there are also higher order QCD corrections beyond the tree-level prediction given by the code. While the inclusion of the higher order effects is beyond the scope of this work we can estimate the possible impact of such effects by enlarging the error corridor of the relic density and determine its impact on the discovery potential of LHC RUN II in this case for a given model point. Thus in table 7, the  $m_1 = m_2$  parameter of Model (i) is adjusted to achieve the range of  $\Omega h^2$  at the 95% confidence interval as given in [46].

Model	$m_1 = m_2$	Gluino	Neutralino	$\Omega_{\text{LSP}} h^2$	Leading SR	$\mathcal{L}$ (fb <sup>-1</sup> )
(i)	1400	706	634	0.122	2jl	14
(i-a)	1396	706	632	0.137	2jl	16
(i-b)	1402	706	635	0.093	2jl	15

Table 7: Effect on Model (i) of perturbing inputs to achieve  $\Omega h^2$  encompassing the 95% confidence range given in [46]. The change in the integrated luminosity needed to discover model (i) with an enlarged range of the relic density is given in the last column and the effect is less than 15% exhibiting that the analysis is robust. All mass parameters are given in GeV.

The connection between LHC physics and dark matter has been discussed in the literature for some time [47] (for a review see [48]). In the context of the gluino-neutralino coannihilation models the connection is even stronger. This is due to the close proximity of the neutralino mass to the gluino mass in this class of models. Thus a determination of gluino mass at the LHC would indirectly imply a determination of the neutralino mass since it lies within 10% of the gluino mass. One can thus make more definitive predictions for the direct detection of dark matter in this case. In general the neutralino has eigencomponents so that  $\tilde{\chi}_1^0 = \alpha \tilde{b} + \beta \tilde{w} + \gamma \tilde{h}_1 + \delta \tilde{h}_2$ , where  $\tilde{b}$  is the bino,  $\tilde{w}$  is the wino, and  $\tilde{h}_{1,2}$  are the two Higgsinos of MSSM. The cross section for the direct detection of dark matter depends on the Higgsino content of the neutralino. The gaugino and Higgsino eigencomponents for Models (i)-(vii) are given in table 8. One may define the Higgsino content of the neutralino by the quantity  $\sqrt{\gamma^2 + \delta^2}$ . From table 8 we see that the Higgsino content of the neutralino is typically small  $< 0.05$ . A small Higgsino content indicates that the neutralino-proton cross sections will be small in the gluino-neutralino coannihilation region. This is discussed below.

Model	$\Delta \times 10^3$	$\beta$	$\gamma$	$\delta$
(i)	< 1	-0.001	0.021	-0.008
(ii)	< 1	-0.001	0.022	-0.009
(iii)	< 1	-0.001	0.017	-0.006
(iv)	1	-0.003	0.042	-0.027
(v)	1	-0.003	0.042	-0.028
(vi)	< 1	-0.001	0.013	-0.005
(vii)	1	-0.002	0.037	-0.024

Table 8: Gaugino and Higgsino eigencomponents of the neutralino for gluino-neutralino coannihilation Models (i)-(vii), where  $\Delta = 1 - \alpha$ .

In table 9 we give a computation of the spin-independent and spin-dependent proton-neutralino cross sections. For the spin-independent case one finds  $\sigma_{p\tilde{\chi}_1^0}^{SI}$  lying in the range  $(1 - 10) \times 10^{-47}$  cm<sup>2</sup>. The next generation LUX-ZEPLIN dark matter experiment [49, 53] is projected to reach a sensitivity of  $\sim 10^{-47}$  cm<sup>-2</sup> [49, 53]. Thus the spin-independent proton-neutralino cross section of the gluino-neutralino coannihilation models lies largely within the sensitivity range of the next-generation LUX-ZEPLIN experiment. A graphical illustration of the spin-independent proton-neutralino cross section is given in figure 11. Here we are using the Models (i)-(vii) except that we allow  $\tan \beta$  to vary between 2-50 and retain only those model points that satisfy the constraint  $\Omega h^2 < 0.123$ . One finds that all of the models lie above the neutrino floor, some by an order of magnitude or more. Thus most of the parameter points of figure 11 appear discoverable by LUX-ZEPLIN. The neutralino-proton spin dependent cross section  $\sigma_{p\tilde{\chi}_1^0}^{SD}$  given by table 9 lies in the range  $(4 - 36) \times 10^{-45}$  cm<sup>2</sup>. Here, LUX-ZEPLIN will have a maximum sensitivity of  $10^{-42}$  cm<sup>2</sup>, which is about two orders of magnitude smaller in sensitivity than what is needed to test the model in this sector.

Model	$R \times \sigma_{p\tilde{\chi}_1^0}^{SI} \times 10^{47}$	$R \times \sigma_{p\tilde{\chi}_1^0}^{SD} \times 10^{45}$	Higgsino content
(i)	0.86	4.3	0.022
(ii)	0.92	4.9	0.024
(iii)	0.49	1.3	0.018
(iv)	7.3	35	0.050
(v)	7.2	30	0.050
(vi)	0.29	0.50	0.014
(vii)	5.5	19	0.044

Table 9:  $R \times \sigma_{p\tilde{\chi}_1^0}^{SI}$  and  $R \times \sigma_{p\tilde{\chi}_1^0}^{SD}$  in units of cm<sup>2</sup> for the gluino-neutralino coannihilation models of table 2, where  $R = \rho_{\tilde{\chi}_1^0} / \rho_c$  with  $\rho_{\tilde{\chi}_1^0}$  the neutralino relic density and  $\rho_c$  the critical relic density ( $R \sim 1$  for the selected gluino-neutralino coannihilation model points). The Higgsino content of the neutralino in each case is also exhibited.

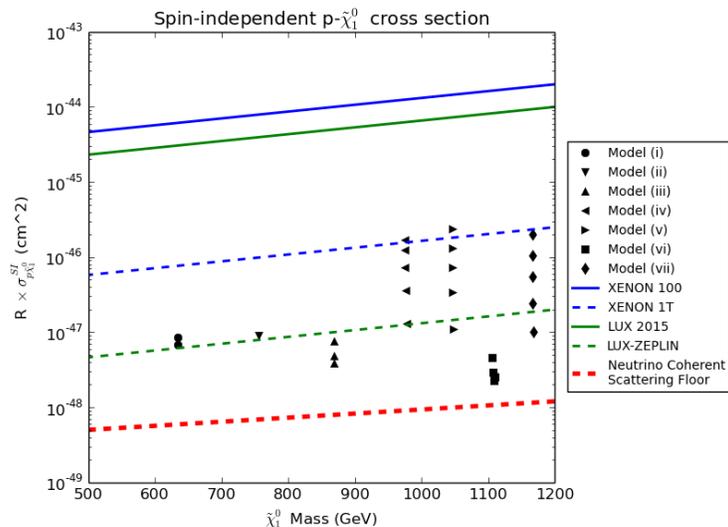

Figure 11:  $R \times \sigma_{p, \tilde{\chi}_1^0}^{SI}$  as a function of the neutralino mass where the vertical scatter points show the dependence on  $\tan \beta$  in the range of  $\tan \beta = 2 - 50$  for a given model. Only those parameter points are admitted which satisfy the constraint  $\Omega h^2 < 0.123$ . Also displayed are the current and projected reaches of the XENON and LUX experiments in the relevant mass range and the neutrino floor [50–53].

## 5 Conclusion

In this work it is shown that in the gluino-neutralino coannihilation region gluino masses as low as 700 GeV consistent with the Higgs boson mass constraint and the relic density constraint would have escaped detection at LHC RUN I and LHC RUN II with  $3.2 \text{ fb}^{-1}$  of integrated luminosity. Our analysis is done within the framework of high-scale supergravity models, allowing for non-universality in the gaugino sector. An illustrative list of models is given in table 2 where the model points all satisfy the Higgs boson mass constraint and the relic density constraint consistent with WMAP and Planck. In the model space analyzed, the gluino is the NLSP, with a mass  $\sim 1.1$  times the LSP mass. The small mass gap between the gluino and the neutralino is needed to satisfy the relic density constraint via gluino-neutralino coannihilation. Requiring that the lightest neutralino supplies all of the thermal relic abundance implies that  $\Delta m = m_{\tilde{g}} - m_{\tilde{\chi}_1^0}$  lies in the range 70-100 GeV over the entire region of the parameter space analyzed in table 2. Because of the small mass gap, the gluino decay modes such as  $\chi_1^\pm q_1 \bar{q}_2$  are suppressed and the decay occurs dominantly to  $\chi_1^0 q \bar{q}$  with the subdominant decay mode being  $\chi_1^0 g$ . In the analysis of the Models (i)-(vii) we have used the signal regions used by the ATLAS Collaboration where an optimization of signal regions was carried out to determine the best regions for gluino discovery in the gluino-neutralino coannihilation region. It is found that among the seven signal regions analyzed the leading ones are  $2j l$  and  $2j m$ . It is found that all the models listed in table 2 are discoverable at LHC RUN II with up to  $\sim 3400 \text{ fb}^{-1}$  of integrated luminosity.

The implications of the gluino-neutralino coannihilation models for the discovery of dark matter was also discussed. As shown in table 9 it is found that the spin-independent neutralino-proton cross section lies in the range  $(1 - 10) \times 10^{-47} \text{ cm}^2$  and this range can be explored in the next-

generation experiments on dark matter, e.g. LUX-ZEPLIN [49, 53]. The observed signal from the gluino-neutralino coannihilation region would be a factor of up to ten times stronger than the one from the neutrino floor [54]. Also, as shown in table 9, the spin-dependent neutralino-proton cross section lies in the range  $(0.4 - 4) \times 10^{-44} \text{cm}^2$ . This is about two orders of magnitude smaller than the sensitivity of LUX-ZEPLIN and thus will be more difficult to observe.
