Abstract

During directional solidification of the solvent in a colloidal suspension, the colloidal particles segregate from the growing solid, forming high-particle-density regions with structure on a hierarchy of length scales ranging from that of the particle-scale packing to the large-scale spacing between these regions. Previous work has mostly concentrated on the medium- to large-length scale structure, as it is the most accessible and thought to be more technologically relevant. However, the packing of the colloids at the particle-scale is an important component not only in theoretical descriptions of the segregation process, but also to the utility of freeze-cast materials for new applications. Here we present the results of experiments in which we investigated this structure across a wide range of length scales using a combination of small angle x-ray scattering and direct optical imaging. As expected, during freezing the particles were concentrated into regions between ice dendrites forming a microscopic pattern of high- and low-particle-density regions. x-ray scattering indicates that the particles in the high density regions were so closely packed as to be touching. However, the arrangement of the particles does not conform to that predicted by standard inter-particle pair potentials, suggesting that the particle packing induced by freezing differs from that formed during equilibrium densification processes.

Interest in directional solidification, or freeze-casting, of suspensions of particles has surged recently owing to the relative versatility, simplicity and cost-efficiency of this process for fabricating complex composite materials [1]. This method has been used to create materials for applications such as tissue scaffolds [2], biomimetic materials [3], photonic structures [4], and metal-matrix composites [5]. In addition, directional solidification has been shown to be effective for water purification [6] and occurs naturally when the ground freezes [7]. In all of these cases, the segregation of particles from the growing solid and the consequent increase of particle concentration in the fluid regions are paramount. In particular, the structure of the regions of segregated particles is important for performance of the material in many applications. This structure occurs on a variety of length scales from the relatively large scale of individual regions of segregated particles to the single particle scale of the packing density of segregated particles. Although most research has focused on the large-scale structure, the particle-scale structure is key to understanding the particle rejection behavior and hence predicting the large-scale structure.

In a very dilute suspension, rejection of single particles from a solidification front is well 31 ³² understood as resulting from fluid flow into the premelted film that separates the particles ³³ from the growing solid (e.g., references [8–10]). In non-dilute suspensions, the same funda-³⁴ mental rejection mechanism is responsible for particle segregation during solidification, but ³⁵ the comprehensive interaction between the growing solid and the large number of particles ³⁶ found in non-dilute suspensions is not well understood. Conceptually, rejection increases 37 the particle concentration in the fluid until the concentration reaches a threshold. Further ³⁸ particle rejection is untenable and the solidification front either becomes unstable or engulfs ³⁹ particles, or both [11]. The morphology of the instability and the mode of particle incor-40 poration creates macro- and microscopic patterns of high- and low-particle-density regions. ⁴¹ Depending upon the freezing conditions, commonly observed patterns include, among oth-⁴² ers, lamellae oriented parallel or perpendicular to the solidification direction, branching or ⁴³ hexagonal networks of nearly pure solid, and seemingly disordered crack-like patterns (e.g., ⁴⁴ references [11–17]). Similarities between these patterns and those formed during drying of 45 colloidal suspensions (e.g., reference [18]) or jamming of suspensions flowing through con-⁴⁶ strictions (e.g., references [19, 20]) suggest that the physics underlying the colloid behavior 47 may be similar as well, though the driving forces in each case differ. Thus, knowledge ⁴⁸ gained from studying structures in freezing colloidal suspensions may be applicable to dense

⁴⁹ colloidal suspensions in diverse circumstances.

Presently, there is no theory that can fully predict the morphology or detailed characteristics of the patterns that form. However, a continuum approach analogous to that describing binary alloy solidification has been successful in predicting the transition from particle pushing to particle capture [11, 15, 16]. This description requires information about the particles near the freezing front, such as the packing density and rate of diffusion in the suspension. Although these quantities have been modelled assuming that the particles behave as hard spheres, it is unknown whether this equilibrium approach to the statistical rechanics of the particles is accurate, or whether the forces associated with the solid growth and concomitant fluid flow affect the particle behavior. Furthermore, a hard sphere pair potential is not a good approximation of the inter-particle interactions for many systems of interest. Therefore, it is important to understand the particle-scale structure and behavior in solidifying colloidal suspensions.

This type of information is difficult to obtain experimentally because the particle concontrations and materials typically involved make the suspensions opaque to visible light. In addition, the particles are often too small to observe individually and the structures that form are three-dimensional. As a result, most studies involve postmortem analysis of samples after sublimation of the solid and sintering or other fixing of the particle structure (e.g., references [2–4, 14, 21, 22]). This gives only a two-dimensional view of the three-dimensional structure, provides only static information about the final particle arrangement, and may be skewed by modification of the structure during sublimation and sintering [23].

A couple of experiments have overcome some of these difficulties by using either a very r1 thin sample cell and transparent materials [24], or applying x-ray techniques (radiography r2 and tomography) to thicker samples [23]. The thin sample chamber produces a quasi-twor3 dimensional system that can be observed with visible light microscopy for sufficiently low r4 particle concentrations, while x-ray techniques can probe inside visibly opaque samples. xr3 ray tomography can even provide a full three-dimensional reconstruction of the samples. All r6 allow samples to be viewed during the freezing process, though the long acquisition time for r7 tomography allows only relatively slow solidification rates [16]. Improved x-ray tomography r8 may relax this restriction [25]. Yet, none of these techniques provide information about the r9 particle-scale structure of the samples. In order to obtain this information, we used small see angle x-ray scattering (SAXS), which provides a Fourier-space representation of the mass ^{\$1} distribution within the samples on the scale of one to several times the particle radius.

Here we present the results of a joint x-ray scattering and direct imaging study. Our experiments benefit from the relative simplicity of a thin sample chamber, which allows sufficient light transmission to produce direct images of the samples. The images provide a basis for interpreting the SAXS intensity data collected before freezing, after melting, and while the samples were frozen. Most importantly, while frozen the data exhibit features related to the structure of the regions of segregated particles that formed during freezing. In particular, we find that the particles are very densely packed, even touching, and their arrangement does not conform to any predicted by standard models of inter-particle intero actions. Therefore, the freezing process must cause particles to pack together in an unusual manner, possibly by creating inter-particle pressures that cannot be attained in the unfrozen solutions. This is an important point that must eventually be accounted for in solidification models, but more generally it raises questions about the arrangement of particles in dense suspensions under external forcing.

95 I. MATERIALS AND METHODS

For our x-ray scattering experiments, we used solutions of colloidal silica spheres dis-⁹⁷ persed in deionized water contained within a specially-designed thin, transparent sample ⁹⁸ chamber. The choice of materials and the experimental setup were each tailored to the ⁹⁹ specific requirements of the x-ray scattering experiment. This section provides the details ¹⁰⁰ of the samples, sample cell, and other aspects of the procedures used in the experiments.

101 A. Materials

¹⁰² Our samples consisted of colloidal silica spheres (Bangs Labs) with radii of about 32 ¹⁰³ nm and polydispersity of about 18%, as determined from scanning electron micrographs ¹⁰⁴ and SAXS data (discussed below). The particles were stabilized against aggregation by ¹⁰⁵ surface-induced ionization. We modified the as-received solutions by centrifuging to sediment ¹⁰⁶ the particles and then replacing the supernatant with deionized water (Fisher Scientific ¹⁰⁷ deionized, ultrafiltered; resistivity 0.5 M Ω /cm) in order to remove as much as possible ¹⁰⁸ of the ionic species (NaOH) added as a stabilizer by the manufacturer, though the final ¹⁰⁹ solutions likely still contained some small amount of free ions [26]. Removal of the dissolved ¹¹⁰ ions is important because they complicate interpretation of the experiments by affecting the ¹¹¹ stability of the solidification front [27], depressing the melting temperature of the solution ¹¹² [7], and congregating in large melt pockets long before bulk melting occurs [26]. Although ¹¹³ removing the dissolved ions could destabilize the colloids and lead to aggregation, we did ¹¹⁴ not observe any indications of this prior to freezing the solutions.

¹¹⁵ During centrifuging, we also adjusted the particle volume fraction of the solutions to ¹¹⁶ $\phi_{HS} \approx 0.07$ –0.08, where ϕ_{HS} is the volume fraction of equivalent hard spheres. This was es-¹¹⁷ timated from the manufacturer's stated volume fraction and the amount of solvent removed, ¹¹⁸ and was verified by the SAXS data assuming hard sphere interactions (discussed below). The ¹¹⁹ actual particle volume fraction based on the physical particle radius was $\phi \approx 0.02$.

120 B. Sample Cell

The sample chamber within the cell was formed by sandwiching an approximately $400 \,\mu m$ 121 ¹²² thick aluminum washer between two copper blocks. Circular pieces of thin polyimide film (Kapton) were epoxied across circular holes on each block to form the viewing area (Fig. 1). 123 A thermoelectric cooling device (TEC, or Peltier cooler) in contact with the copper blocks 124 controlled their temperature. A second TEC controlled the temperature of a copper arm 125 (the "cold finger") that made thermal contact with the sample through physical contact with 126 the outside of one of the windows. The cold finger had a cylindrical tip with inner diame-127 ter 2 mm and outer diameter 4 mm. By maintaining the temperature of the blocks above 128 0°C while that of the cold finger was lowered below 0°C, we created a nearly isothermal 129 region within the cold finger inner diameter and a temperature gradient region between the 130 cold finger outer diameter and the blocks. This allowed continuous contact with a reservoir 131 of unfrozen solution, which helped alleviate pressure build-up during freezing and due to 132 frost heaving when frozen [28]. The temperature control system and calibrated platinum 133 resistance thermometric devices (Pt RTD's) provided $\pm 0.001^{\circ}$ C precision and $\pm 0.05^{\circ}$ C ac-134 curacy in temperature measurement, as well as temperature stability of $\pm 0.001^{\circ}$ C over 10 135 $_{136}$ minutes. Finally, the actual thickness of the sample chamber varied between about 200 μ m $_{137}$ and 400 μ m due to the flexibility of the windows combined with manual positioning of the 138 cold finger abutting one window.

FIG. 1. (Color online) The image on the left shows the entire sample cell with the sample chamber and cold finger tip enlarged in the top right hand corner. In the lower right hand corner, the schematic diagram shows a plan-view of the cold finger tip with the approximate locations of x-ray data collection (LE = left edge, LC = left center, C = center, RC = right center, and RE = rightedge).

139 C. Procedure

The x-ray scattering experiments were performed at beam line 8-ID of the Advanced 141 Photon Source at Argonne National Laboratory. Details of the beam line are provided by 142 references [29] and [30], but we will summarize the important aspects in this section along 143 with the details of our particular experiment at this beam line.

For the x-ray experiments, the sample cell described above was placed in the beam line, which was evacuated to about 10^{-2} torr. Evacuating the beam line minimizes stray scattering the of the x-ray beam from air or water vapor as it approaches the sample and then as the scattered x-rays travel to the detector. The fluid inside the sample chamber remained at take atmospheric pressure because it was connected to the ambient atmosphere via the fill lines.

¹⁴⁹ In four separate trials, we investigated four different samples, each prepared in the same ¹⁵⁰ manner and labeled samples 1–4 in the results below. Each of the samples was frozen by $_{151}$ lowering the cold finger temperature to around -30° C, while the temperature of the blocks was maintained at a constant 1°C throughout all experiments. The samples cooled at rates up to 1°C/s at higher temperatures and nearly 0.25°C/s at lower temperatures. Ice typically 153 nucleated between -20° C and -30° C, manifested by a slight change in the rate of decrease 154 of the temperature due to the release of latent heat. After freezing, we studied the samples at 155 temperatures between -2° C and 0° C with intervals as small as 0.05° C, always increasing the 156 temperature over time. Thus, temperature increased as the sample age increased, though not 157 continuously and not at precisely the same rate in all experiments. As a result, effects due 158 to the increasing temperature and aging of the samples are convoluted in our experiments. 159 We acquired x-ray scattering data at many temperatures before freezing, immediately 160

¹⁶¹ after freezing, and as the temperature was increased towards 0°C. We could not acquire ¹⁶² data during freezing due to the unpredictable timing of ice nucleation and the speed of ice ¹⁶³ growth in the highly supercooled suspension. At each temperature, the x-ray beam was ¹⁶⁴ directed through the inner diameter of the cold finger and positioned at each of five different ¹⁶⁵ locations across this region as shown in Fig. 1. Thus, the x-ray experiments interrogated ¹⁶⁶ several parts of the isothermal region of the samples.

¹⁶⁷ The x-rays we used had an energy of approximately 7.4 keV for a wavelength of about ¹⁶⁸ 0.17 nm. The beam cross-section was roughly 20 μ m by 20 μ m with a total incident flux ¹⁶⁹ of approximately 4 × 10⁹ photons/s. For comparison, the cell thickness is several hundred ¹⁷⁰ μ m and the particle radius is only 0.032 μ m, so there are many millions of particles in the ¹⁷¹ scattering volume.

The scattered x-rays were collected by a charge-coupled device (CCD) camera, described irightarrow in reference [30]. The CCD detector was exposed to scattered x-rays for 0.015 s per frame. To form a data set, a total of 500 frames were collected over about 110 s. During the readout irightarrow to be between frames and whenever data were not being acquired, the sample was blocked from x-ray illumination to limit radiation damage, which may induce melting [31].

Each frame in a particular data set was analyzed to create false color images of the scat-177 Each frame in a particular data set was analyzed to create false color images of the scat-178 tered intensity. We verified that the scattering pattern was isotropic and did not change 179 significantly while acquiring a set of images. Therefore, the images could be averaged az-180 imuthally and over time to produce the intensity as a function of scattering vector I(q). 181 Finally, this curve was normalized by the incident flux, detector efficiency and area, and the 182 solid angle spanned by the detector. In the results presented below, we report the normalized 183 intensity curve

$$I_N(q) = d \operatorname{Tr} \phi V_{part} (\Delta \rho)^2 P(q) S(q) \equiv A P(q) S(q), \qquad (1)$$

¹⁸⁴ where d is the cell thickness, Tr is the transmission coefficient, V_{part} is the average particle ¹⁸⁵ volume, and $\Delta \rho$ is the electron density difference between silica and water or ice. The ¹⁸⁶ coefficients are grouped together into the amplitude A. We did not normalize by the sample ¹⁸⁷ thickness or transmission because, due to the pressure difference a slight curvature was ¹⁸⁸ present, so the sample thickness was not known precisely at each sampling position. In ¹⁸⁹ what follows, we will refer to the normalized intensity as simply I(q). A more comprehensive ¹⁹⁰ background to x-ray scattering can be found in the appendix and the references therein.

191 II. DIRECT IMAGING

Before delving into the SAXS results, we present direct images of freezing and frozen colloidal suspensions under conditions similar to those used in the x-ray scattering experiments. These images provide a reference for interpreting the features in the SAXS intensity curves.

¹⁹⁶ We used the same sample cell and type of colloidal solutions in the direct imaging ex-¹⁹⁷ periments as in the SAXS experiments. In addition to colloidal samples, we also observed ¹⁹⁸ samples without particles, simply pure deionized water. The cell was situated between the ¹⁹⁹ light source and the camera, thus the samples were viewed in transmission. Images were ²⁰⁰ focused onto a CCD detector (Unibrain Fire-i) with a 4x microscope objective lens resulting ²⁰¹ in an image scale of about 6 μ m per pixel.

We froze the samples by lowering the temperature of the cold finger either directly with TECs or with liquid nitrogen. The samples typically froze at temperatures between -6° C and -25° C, though the freezing temperatures of individual samples had a high degree of uncertainty (up to $\pm 2^{\circ}$ C). In all cases, the water was supercooled when ice nucleated, resulting in two stages of ice growth: a rapid stage I with a cellular or dendritic morphology, and a slower stage II with an apparently planar morphology.

During stage I, the low temperature of the sample caused rapid solidification and ice growth into a solution below the melting temperature T_m , leading to an unstable solidification front and a cellular or dendritic ice growth morphology [11, 16, 32, 33]. Figure 2 ²¹¹ shows two sets of images obtained from movies of the sample freezing that illustrate this ²¹² stage of ice growth in pure water (a) and a colloidal solution (b). The ice growth is cellular ²¹³ or dendritic with a linear pattern of alternating dark and light lines visible inside the cold ²¹⁴ finger in both samples. Because the entire field of view often froze in the time span of only ²¹⁵ a few frames (at frame rates of 7.5 or 15 fps), estimates of the freezing rates have large ²¹⁶ uncertainty. However, the values mostly fall between 10 mm/s and 40 mm/s, which agree ²¹⁷ fairly well with the morphology diagram for pure water in reference [33].

Stage I freezing ended when the entire sample had been warmed to T_m through release 218 ²¹⁹ of latent heat of solidification. After this time, further freezing required further removal of ²²⁰ heat from the sample, which was effected by the TECs. We then observed an apparently ²²¹ planar ice front growing radially inwards and outwards from the cold finger, freezing any ²²² water that remained after stage I. Figure 3 contains a sequence of images showing this ²²³ stage II ice growth, during which the ice edge moves radially inwards at a constant rate ²²⁴ of 0.085 mm/s. Because the solidification rate during stage II is slower, measurements are ²²⁵ much more accurate. All freezing rates are nearly constant throughout stage II ice growth and vary between about 0.1 mm/s and 1 mm/s among the samples. Although the stage II 226 ice front appeared to be stable and planar, in fact it may have been unstable, just with a 227 wavelength below the resolution of our imaging setup. Previous work [22] has shown that for 228 solidification rates in the range of our experiments, the wavelength of the instability drops 229 below $10 \,\mu\text{m}$, which we would not be able to resolve. 230

During stage II, the linear pattern of light and dark stripes formed during stage I dis-231 appears from pure water samples, whereas it persists in colloidal samples. This pattern is 232 evident both in Fig. 3 and in the first image of the sequence in Fig. 4. Because the samples 233 were viewed in transmission, areas of high particle density should appear dark whereas areas 234 of low particle density should appear light. Therefore, we interpret the light and dark stripes 235 present in colloidal samples as a pattern of high and low particle density imposed by the 236 ice during freezing. In the pure water samples, they are simply an optical effect due to the 237 edges of the dendrites, which disappear once the stage II ice growth has solidified all water 238 ²³⁹ remaining between the dendrites.

These observations indicate that the particles were rejected to the inter-dendrite regions during stage I and then engulfed by the ice during stage II. The critical freezing rate above which a single particle at a planar ice interface will be engulfed by the growing solid depends

FIG. 2. (Color online) These images show two sets of before (time t = 0 s) and after (t > 0 s) snapshots from movies of stage I ice growth. The images in (a) show pure water, whereas those in (b) show a colloidal solution of silica spheres as described above, but with particle radius 142 nm. We note that we did not observe any significant differences in the direct imaging experiments between the behavior of solutions of these larger particles and solutions of the smaller particles (as used in the x-ray scattering). Ice dendrites are visible in both sets: dark in (a) and lighter areas between dark regions of concentrated particles in (b).

FIG. 3. These images show a sequence of snapshots of stage II solidification for a sample of 142 nm particles. In areas where stage II ice has formed the sample appears darker. The stage II ice edge is marked by a dark rim of particles being pushed ahead of the ice, which form a dark spot at the center upon complete solidification.

²⁴³ upon the particle size and the specific intermolecular interactions between the particle and ²⁴⁴ the solid [10]. Using the magnitude of the interaction between glass particles and ice determined by reference [17], we find that the particles should have been rejected from the 245 ²⁴⁶ growing ice during both stages [26]. Indeed, during stage I the particles were rejected into ²⁴⁷ the inter-dendrite regions, and during stage II some of the particles not in the inter-dendrite ²⁴⁸ regions were evidently rejected as dark patches appeared at the center of the cold finger in some samples. However, the particles rejected to the inter-dendrite regions were engulfed 249 by stage II ice growth, perhaps by trapping between the dendrites [5, 16] or possibly due to 250 their inclusion in large particle aggregates [26]. Such effects are not included in the model 251 of reference [10], thus highlighting the need for ongoing work. In summary, the process 252 of freezing supercooled colloidal suspensions in our experimental setup results in a linear 253 ²⁵⁴ pattern of high- and low-particle-density regions due to the unstable freezing morphology.

The width of the stripes was typically tens of μm ; for the sample shown in Fig. 4, 255 $_{256}$ initially the light (low density) regions were on average 17 μ m across and the dark (high $_{257}$ density) regions were on average $28\,\mu\mathrm{m}$ across. However, these patterns and the widths of the respective regions changed as the temperature increased and the samples aged. We 258 observed the evolution of the samples at different temperatures between $-2^{\circ}C$ and $0^{\circ}C$ 259 over time scales ranging from several hours up to one week. In general, the light areas 260 became more rounded, and the linear dark features tended to merge with each other, their 261 edges becoming simultaneously more sharply defined. Figure 4 contains a sequence of images 262 ²⁶³ illustrating this evolution. Our direct observations and dynamic x-ray scattering suggest that ²⁶⁴ this evolution is driven by grain boundary motion due to coarsening of the polycrystalline ²⁶⁵ ice in the samples [34].

²⁶⁶ Upon melting, we observed that many dark objects up to $100 \,\mu\text{m}$ in size sedimented out ²⁶⁷ of the solution. Presumably, these were aggregates of individual particles bound together ²⁶⁸ during the freezing or subsequent evolution processes (images provided in reference [26]).

Finally, we note that all of the observations described above occurred in a qualitatively similar manner despite differences in the initial freezing temperature and how the temperature changed over time after freezing. While lower freezing temperatures resulted in faster solidification velocities [26], and thus presumably differences in particle incorporation as well as the micrometer-scale structure [23], our direct imaging experiments had insufficient resolution to quantify these variations. However, as we will describe in the next section,

FIG. 4. These images show a sequence of snapshots of a frozen solution of 32 nm particles over time with the sample ages and temperatures indicated. The small dark spots near the cold finger are air bubbles. Because the water was not degassed before freezing, air gradually exolves from the ice.

²⁷⁵ such differences do not significantly affect the particle-scale structure, particularly the inter-²⁷⁶ particle spacing.

In summary, the direct imaging experiments provide general information about the freez-²⁷⁷ ing process in our system. After deep supercooling, the initial stage of solidification is unsta-²⁷⁹ ble with particles being rejected to the regions between ice dendrites to form a linear pattern ²⁸⁰ of high and low particle density. During the second stage of solidification, this pattern is ²⁸¹ locked in as an apparently planar ice front grows across the cell. As the frozen samples ²⁸² evolve, the high-particle-density regions rearrange due to the motion of grain boundaries ²⁸³ from ice crystal coarsening. These observations serve as a framework for understanding the ²⁸⁴ results of the x-ray scattering experiments, which provide quantitative information about ²⁸⁵ the particle-scale structure in these macroscopic features.

286 III. SAXS RESULTS

The primary result of SAXS is the scattered intensity I(q). Figure 5 shows typical 287 examples of I(q) for a sample before being frozen (circles) and when frozen (squares). The 288 unfrozen data decrease smoothly as q increases, whereas the frozen data have two features: 289 a peak at high q and an upturn at low q. For all temperatures at which the sample was 290 ²⁹¹ frozen, the intensity maintained the same general form with these two features, though the position and width of the features changed. Upon melting, the scattered intensity reverted 292 to the unfrozen form observed before the samples were frozen, though the details of the 293 shape had changed. These data reflect the structural properties of the samples such as the 294 particle size, shape, and inter-particle spacing. By fitting the intensities to a theoretical 295 model (unfrozen data) and an empirical function (frozen data), we were able to quantify 296 these structural properties and monitor how they evolved as the sample temperature was 297 ²⁹⁸ increased and the samples aged.

299 A. Unfrozen Intensity

For the unfrozen intensities, we obtained the particle radius, polydispersity, and volume fraction by fitting the data to a function of the form I(q) = A P(q) S(q) from equation 1, where A is a q-independent coefficient signifying the amplitude of the scattering, P(q) is the

FIG. 5. SAXS intensity versus scattering vector taken at the center position from sample 1 before being frozen (circles) and at $T = -2.00^{\circ}$ C when frozen (squares). The solid curve represents the fit of the unfrozen data to a polydisperse sphere form factor and monodisperse hard sphere structure factor with R = 32.4 nm, z = 31, A = 294, $R_{HS} = 53.0$ nm, and $\phi_{HS} = 0.073$ as described in the text. For comparison, the dotted line shows only the form factor with the same parameters as above, but an arbitrary amplitude. For clarity the unfrozen data have been offset from the frozen data by multiplication with a constant coefficient.

³⁰³ particle form factor, and S(q) is the structure factor. Though the particles are not perfectly ³⁰⁴ spherical, we used a standard form factor for polydisperse spheres [35] that depends on the average particle radius R and the polydispersity parameter z. This form factor is based on a 305 Schulz-Zimm distribution of individual particle radii R_p in which z describes the width of the 306 distribution. In this case, the mean square deviation is given by $\overline{R_p^2}/(z+1)$ where $R = \overline{R_p}$ 307 35]. For the structure factor we used a function for monodisperse spheres of radius R_{HS} 308 at volume fraction ϕ_{HS} interacting via a hard sphere potential [29]. For each unfrozen data 309 set, the fitting was performed using an iterative grid search method to find the parameters 310 that minimized the mean squared residual. Due to the large range of intensity values, the 311 ³¹² logarithm of the data was used to determine the residuals. We also visually inspected each ³¹³ fit to ensure quality. The solid curve in Fig. 5 shows this fit to a typical data set.

Altogether there are five parameters in the fitting equations: the average particle radius 315 R, the polydispersity z, the hard sphere radius R_{HS} , the hard sphere volume fraction ϕ_{HS} , ³¹⁶ and the amplitude constant A. Across all samples and positions, the average particle radius was 32 ± 1 nm and the polydispersity 29 ± 3 both before freezing and after melting, for 317 a spread of about 18% around the average radius (as given above in section IA). The 318 $_{319}$ hard sphere radius was typically 53 ± 1 nm with the change between the pre-freezing and after-melting values negligible compared with uncertainty in the fitting. In contrast, the 320 ³²¹ hard sphere volume fraction was typically between 0.07 and 0.09 before freezing, but usually $_{322}$ dropped to between 0.03 and 0.07 after melting. We do not discuss A here because without ³²³ measuring the absolute scattered intensity, changes in this parameter cannot be interpreted unambiguously. Thus, most parameters did not change significantly from before freezing 324 to after melting (to within the uncertainty in the fit), except that the hard sphere particle 325 volume fraction decreased by a factor of 2 or more. 326

The average particle radius and the polydispersity reflect the actual physical extent of 327 the particles. Thus, the near constancy of these parameters indicates that the physical 328 ³²⁹ size of individual particles and distribution of those sizes did not change during freezing or 330 subsequent evolution. The hard sphere radius, on the other hand, represents the effective ³³¹ radius of the particles in their interactions with each other (assuming they interact according $_{332}$ to a hard sphere potential). Because R_{HS} is larger than R, the particles apparently behaved as if they were larger than their physical dimension. As a result, ϕ_{HS} overestimates the actual particle volume fraction ϕ . The two volume fractions can be related by $\phi = \phi_{HS} \left(R/R_{HS} \right)^3$. 334 This gives initial actual volume fractions of about 0.015 - 0.02 and final actual volume 335 fractions between 0.007 and 0.015. As R_{HS} did not change significantly throughout the 336 experiment, the decrease in ϕ_{HS} represents a real decrease in the bulk particle concentration 337 from before freezing to after melting. 338

339 B. Frozen Intensity

For the frozen data, we isolated the structure factor by dividing the intensities by ³⁴⁰ For the form factor used for the unfrozen solutions with R = 32 nm and z = 29. Because ³⁴² I(q) = AP(q) S(q), dividing by P(q) leaves a measured structure factor $S_m(q) = AS(q)$. ³⁴³ Examples of $S_m(q)$ are shown in Fig. 6. Like the full intensity profile, the measured struc-³⁴⁴ ture factor has a clear peak at high q-vectors and an upturn at low q-vectors. Whereas ³⁴⁵ the upturn is more prominent in the full I(q) because it is enhanced by the large values of

FIG. 6. Measured structure factors versus scattering vector taken at the left edge position from sample 4 at $T = -1.20^{\circ}$ C (circles) and $T = -0.60^{\circ}$ C (squares). Solid curves represent the Gaussian fits of the main peak as described in the text. Along the top of the plot, the horizontal axis is labeled in units of qR.

³⁴⁶ P(q) at low q (see dashed line in Fig. 5), conversely the peak is enhanced in $S_m(q)$. The ³⁴⁷ upturn in the structure factor at low scattering vectors represents structure on length scales ³⁴⁸ larger than several times the particle radius. The peak at higher scattering vectors reflects ³⁴⁹ structure on the single particle length scale, giving information about the particles' nearest ³⁵⁰ neighbors.

In order to obtain information about the particle packing, we attempted to fit $S_{m}(q)$ 351 with a variety of common structure factors with A as a free parameter. We were unable 352 to obtain acceptable fits with structure factors derived from a monodisperse hard sphere 353 potential [29], polydisperse hard sphere potential [36, 37], sticky hard sphere (square well) 354 potential [38, 39], or Coulomb repulsion [40]. In part, the failure of the structure factor 355 models resulted from their inability to reproduce the upturn at low q. Therefore, we also 356 investigated fitting only the high q-vector peak, yet we were still unable to obtain acceptable 357 $_{358}$ fits with any of the hard sphere models. In a further attempt to fit the low q upturn, we $_{359}$ modified the form factor by including a fractal cluster term [41] or a q^{-4} dependence [39], 360 but neither improved the fits.

³⁶¹ Instead, we fit the main, high *q*-vector peak with a Gaussian function given by

$$I(q) = \delta + A \exp\left[-\left(q - q_{peak}\right)^2 / \sigma^2\right],\tag{2}$$

where in δ is the *q*-independent offset, *A* is the *q*-independent peak height, q_{peak} is the peak location, and σ controls the peak width. In order to obtain reliable fits, we only used data between chosen low- and high-*q*-vector cutoffs. The low-*q*-vector cutoff was that scattering vector at which the measured structure factor reached its minimum value. The high-*q*-vector cutoff was defined as q = 0.14 nm⁻¹. We fit the plain values of $S_m(q)$ rather than their logarithm to emphasize fitting of the peak. The fitting was performed using an iterative grid search method to minimize residuals. As with the unfrozen data, we visually inspected the resulting fits to ensure good quality. The solid curves in Fig. 6 illustrate these fits.

We performed this Gaussian fitting on all data sets for which the samples were frozen and 370 examined the resulting fit parameters as a function of temperature (examples are shown in 371 Fig. 7). In general, all data exhibit similar trends, though there is some variation among 372 ³⁷³ positions within a given sample and among different samples. This variation is produced by the inherently stochastic nature of the ice nucleation process, the unstable ice growth 374 morphology, and the process of ice crystal coarsening in the polycrystalline ice. These 375 processes lead to spatial variations in the total number of particles contained within the 376 scattering volume and differences in how this number changes with time and temperature. 377 Such variation in particle number primarily affects the fitted values of A and δ . 378

We find that the peak position and peak width, which represent the predominant inter-379 particle spacing (nearest neighbor distance) and the distribution of inter-particle distances, 380 ₃₈₁ are fairly constant at $q_{peak} \approx 0.123 \text{ nm}^{-1}$ ($q_{peak}R \approx 3.94$) and $\sigma \approx 0.017 \text{ nm}^{-1}$, respectively, though the peak width appears to increase slightly in some cases. This indicates that the 382 average inter-particle distance remained fairly constant while the samples were frozen. The 383 increasing peak width indicates that the distribution of inter-particle distances widened 384 slightly. Surprisingly, variations in ice nucleation temperature, and hence freezing rate, 385 do not translate into variations in particle spacing. The peak amplitude shows a very clear 386 decreasing trend as the temperature increases, while the offset does not exhibit a clear trend. 387 The offset is simply related to the overall amount of scattering, which we expect to change 388 389 between data sets as particles move into or out of the scattering volume. The decreasing ³⁹⁰ peak amplitude indicates a decrease in the number of nearest neighbors. When combined

FIG. 7. Peak fit parameters versus temperature from the center position of two different samples (circles, sample 1; squares, sample 2). The peak position is in (a), the peak width is in (b), the peak amplitude is in (c), and the peak offset is in (d).

³⁹¹ with the increasing peak width, this suggests an increase in heterogenity of particle spacing ³⁹² as the temperature increased and the samples aged.

Altogether, SAXS reveals that the scattered intensity, and hence the sample structure, 393 changed very dramatically when the samples froze and continued to evolve while the samples 394 were frozen. The changes in I(q) from before freezing to after melting indicate that the 395 volume fraction of particles within the bulk solution decreased significantly. While the 396 samples were frozen, the steady position of the high q-vector peak shows that the average 397 nearest neighbor distance remained fairly constant. The slight widening of the peak and the decrease in its amplitude suggest that the distribution of inter-particle distances widened 399 400 and became more heterogeneous. In the next section, we interpret these results within the 401 context of the direct images obtained from our laboratory experiments and with respect to 402 established models for the structure factor.

403 IV. DISCUSSION

These SAXS results provide quantitative information about the structures observed in 405 the direct images, and conversely, the direct imaging experiments provide a qualitative 406 framework for interpreting the SAXS results. In particular, direct observation revealed a 407 linear pattern of high and low particle density that formed during the dendritic freezing 408 of the colloidal solutions at high levels of supercooling. This pattern subsequently evolved 409 as the temperature increased and the samples aged, with regions of high density joining 410 together and regions of low density enlarging. Furthermore, we observed particle aggregates 411 sedimenting out of solution as the samples melted. Each of these observations can be 412 identified with and quantified by features in the SAXS results.

For the following discussion it is important to note the relative size of the x-ray beam as 414 compared with the pixel size in the direct images in order to maintain the proper perspective 415 on the structures probed by the x-ray scattering. As the size of a single pixel in the direct 416 imaging setup was approximately $6 \,\mu$ m square, the entire x-ray beam (approximately $20 \,\mu$ m 417 square) covered roughly an equivalent area of 9 pixels (3 pixels by 3 pixels) in the direct 418 images. Therefore, the scattering volume probed by the x-rays, and consequently the struc-419 tures inferred from the scattering data, are comparable to the smallest details that could be 420 observed in the direct imaging experiments.

We first discuss the scattering data from unfrozen solutions. These data were fit to a 421 ⁴²² model based upon polydisperse spherical particles that interacted as if they were monodis-⁴²³ perse hard spheres. In fact, before being frozen the colloids likely interacted according to ⁴²⁴ DLVO theory [42] because the attractive van der Waal's interaction at short range was counteracted by the long-range repulsive electrostatic interaction arising from surface-induced 425 ionization. Generally, silica colloids have silanol (SiOH) surface groups which ionize in so-426 ⁴²⁷ lution to form negatively charged SiO⁻ groups that give the particles an overall negative charge and hence stabilize the solution [43]. The H⁺ ions that dissociated from the surface 428 ⁴²⁹ mix with any other ions in the water and form a diffuse layer of higher ion concentration ⁴³⁰ surrounding each of the particles with characteristic thickness given by the Debye length [42].431

Several studies of colloids have found differences between the physical particle radius 432 as measured by electron microscopy and the actual radius or effective hard sphere radius 433 measured by static or dynamic light scattering [44–48], and indeed charge stabilized colloids 434 have been found to behave as effective hard spheres [49]. In our system, the SAXS data show 435 that when not frozen the particles could be treated as hard spheres with an effective hard 436 ⁴³⁷ sphere radius somewhat greater than the actual particle radius. Presumably, the effective ⁴³⁸ hard sphere radius is larger than the actual radius due to the cloud of ions surrounding the particles, but an exact relationship between the effective hard sphere radius and the Debye 439 440 length is not known. Thus, we attribute the difference between R and R_{HS} to the dissolved ⁴⁴¹ ionic species remaining in the solutions.

Next, we consider the change in ϕ between the SAXS measurements made before freez-442 ⁴⁴³ ing the samples and after melting. The particle volume fraction obtained after adjustment 444 from the fitted ϕ_{HS} tended to drop from about 0.02 before freezing to around 0.01 after melting. This decrease indicates that after being frozen and melted, the bulk solution con-445 tained less than half as many particles as it contained before being frozen. The missing 446 particles presumably sedimented as aggregates, as we observed in the direct imaging ex-447 periments. Because the particles used in our experiments have a very small Peclet number 448 (about 10^{-5}), Brownian motion is sufficient to keep individual particles suspended almost 449 ⁴⁵⁰ indefinitely. However, the increased mass of particle aggregates could cause sedimentation ⁴⁵¹ on experimentally relevant time scales [26]. Therefore, the SAXS results from the unfrozen 452 samples imply that about half of the particles originally in the solution ended up in long⁴⁵³ lived aggregates and subsequently sedimented upon melting of the ice. The aggregates most ⁴⁵⁴ likely formed in the high particle density regions created by rejection of particles from the ⁴⁵⁵ ice dendrites. This is supported by the interpretation of the SAXS data collected while the ⁴⁵⁶ samples were frozen.

The scattered intensity from frozen samples had two primary features associated with 457 structure possessing two distinct primary length scales. The high scattering vector peak 458 corresponds to the inter-particle spacing of colloids within the high density regions and 459 the low scattering vector upturn is related to the size of the high density domains. If we 460 could extend our measurements to lower scattering vectors, we would expect to find that the 461 upturn is in fact a peak and its position would give the size of the high density domains (as in 462 $_{463}$ references [50-52]) or the spacing between them. In the present experiments, the minimum $_{464}$ q gives a lower bound for the size of these features: $2\pi/q_{min} = 2\pi/0.02 \text{ nm}^{-1} = 314 \text{ nm},$ or approximately 10 times the particle radius. Further measurements at lower scattering 465 vectors would also help clarify the medium-scale structure of the high density regions, i.e., 466 467 the arrangement of particles on length scales greater than that of a single particle, but still within a single high density region. Although the failure of the fractal cluster model to fit 468 the low-q upturn in our data suggests that structure at this scale is not fractal, there are 469 ⁴⁷⁰ insufficient data to rule this out or to advance other possibilities.

On the other hand, the high scattering vector feature provides more reliable information 471 because the full peak falls within our accessible q-range. This peak reflects how the particles 472 ⁴⁷³ packed as they were rejected during freezing. We can rule out a crystalline arrangement of 474 the particles because the peak is too broad. We did not expect that the particles in the 475 present experiments would pack this way due to their large polydispersity, which is known to ⁴⁷⁶ inhibit colloidal crystallization [53–55]. In addition, colloidal crystallization is an equilibrium process requiring some amount of time to proceed. Although an ordered particle packing 477 has been observed in at least one directional solidification experiment [4], the densification 478 479 of the particles upon rejection during freezing in our samples was most likely too rapid to permit this process [56]. Therefore, the particles in the high density regions packed in a 480 ⁴⁸¹ predominantly amorphous or random arrangement.

Particles in an amorphous packing, like particles in a colloidal crystal, are characterized 483 by an average inter-particle distance though the variation around this average distance is 484 greater in amorphous packings than in crystalline ones. The position of the SAXS peak is ⁴⁸⁵ approximately related to this distance by $2\pi/q_{peak}$, which gives an interparticle distance on ⁴⁸⁶ the order of the particle diameter for our data. Therefore, we conclude that the particles in ⁴⁸⁷ the high density regions were generally in contact with their nearest neighbors. However, this ⁴⁸⁸ is insufficient to determine the particle volume fraction. Knowing that on average particles ⁴⁸⁹ were in contact with their nearest neighbors offers no information about how many nearest ⁴⁹⁰ neighbors an average particle contacts, which is related to ϕ .

Typically the volume fraction is quantified through the model for S(q). However, our 491 measured structure factors did not conform to structure factors based on common particle 492 pair potentials. Therefore, we estimate the volume fraction by analogy with another experi-493 ment on dense, polydisperse colloidal suspensions. Pham and colleagues [57] suggested that 494 a shift of the peak position in their scattering data from $qR \approx 3.8$ to $qR \approx 4.0$ corresponded 495 to a change in the local particle volume fraction from 0.60 to 0.69, the random close packing 496 ⁴⁹⁷ limit for their system. The enhancement above the often-quoted random close packing value of 0.64 was attributed to particle polydispersity. We note that they did not compare their 498 data with any models. Based on their empirical relation and the location of our peak at 499 $_{500}$ $qR \approx 3.94$, we estimate that the particles in the high density regions had a volume fraction near 0.66. This is similar to the predictions from simulations for spheres of similar poly-501 dispersity, which range from 0.66 to 0.68 [58, 59]. Thus, the particles in the high density 502 regions were likely at their close-packing limit. 503

With this knowledge, we can explain the formation of the observed particle aggregates. 504 ⁵⁰⁵ Before the particles can aggregate though, they must be brought into contact. In order to bring the particles into contact, the ice must have exerted a force on the particles sufficient to 506 overcome the repulsion between two particles resulting from the surface charges and double 507 layer. From frost heaving of soils the maximum overpressure at which heaving stops has 508 been measured at about 11 atm per °C of cooling below T_m [7]. For the present experiments 509 where freezing occurred below -20° C the pressure on the particles may have been larger 510 than 200 atm, which is much larger than the expected electrostatic repulsion. Thus, it is 511 reasonable that the ice should be able to overcome the repulsive force between the particles 512 and push them into close contact. 513

Once this repulsion was overcome and the particles were forced into contact by the ice ⁵¹⁵ dendrites, the attractive van der Waal's force should have dominated the interaction, allow-⁵¹⁶ ing the particles to form aggregates. Using the Hamaker constant for fused quartz and a ⁵¹⁷ separation of 0.25 nm (the approximate size of a water molecule), the attraction potential ⁵¹⁸ between two particles is estimated to be -9.4×10^{-20} J, or about $25k_BT$ at $T = 0^{\circ}$ C, where $_{519}$ k_B is Boltzmann's constant [42]. This is sufficient to maintain the aggregates' integrity well s20 above the melting temperature. Alternatively, once the particles were forced into contact ⁵²¹ they may have fused together chemically or physically due to damage near the inter-particle contacts, which may also have been responsible for the failure of standard structure factors 522 to fit our data. In either case, this suggests that the aggregates were the direct result of 523 particle rejection to the inter-dendrite regions during freezing. Combined with the SAXS 524 results from the solutions when unfrozen, we can then estimate that at least half of the 525 particles in the solution ended up in these high density regions. However, this is a lower 526 bound, and in fact nearly all of the particles may have been caught between the dendrites, 527 but some were individually engulfed by the ice or subsequently stripped from the aggregates 528 by dynamic processes [34]. 529

The strong forcing of the particles by the growing ice during freezing may also be respon-530 ⁵³¹ sible for the failure of standard structure factors to model our scattering data. This failure implies that the particle configuration within the high-particle-density regions was differ-532 ent from those that occur in high density colloidal fluids (c.f. reference [29]), glasses (c.f. 533 reference [60]), or gels (c.f. reference [61]) even though the underlying particle interactions 534 are similar (long-range repulsive or hard sphere interactions and short-range attraction). In 535 particular, the peak in our data generally occurred at higher scattering vectors and was 536 broader and taller than the peak predicted by any of the standard models. This means 537 538 that our samples tended to be more heterogeneous with respect to the inter-particle spacing 539 and have a greater number of nearest neighbors than expected from these models. Such ⁵⁴⁰ differences may be related to the forcing present during freezing.

Although much work has been directed at studying the influence of shear flow on structure ⁵⁴² in various colloidal materials (e.g., references [62–64]), relatively little work has been done ⁵⁴³ on other types of external forcing that are more comparable to what the particles experience ⁵⁴⁴ during freezing. One example, though, is the experiment of Kurita and Weeks [65]. They ⁵⁴⁵ examined a layer of randomly close packed, sedimented particles using confocal microscopy ⁵⁴⁶ and calculated a structure factor from the real-space positions of the particles. Their system ⁵⁴⁷ had an overall volume fraction of about 0.646 with small, locally ordered regions having ϕ ⁵⁴⁸ up to about 0.68 and they found that the resulting S(q) had a primary peak near $qR \approx$ 549 3.93 (versus 3.94 for our system). This peak position is higher than expected for hard 550 spheres at these volume fractions, but they did not attempt to fit their structure factor to ⁵⁵¹ any models, so differences in the shape are not known. Sedimentation involves a gradual ⁵⁵² increase in the particle density and compression of the colloidal fluid, similar to what happens ⁵⁵³ during freezing when the growing solid continually squeezes the particles into the shrinking volume of unfrozen liquid. Therefore, we might expect that our samples had a structure 554 with characteristics similar to that of the sedimented layer: very high densities with some 555 local variability. However, the rate of compression during freezing is much higher than in 556 sedimentation, which could lead to more variability in the packing and a broader structure 557 factor peak. In addition, the morphology of ice growth and the kinetics of particle segregation 558 ⁵⁵⁹ could also lead to more heterogeneity in the packing.

Altogether, our observations have several implications for our understanding of direc-560 ⁵⁶¹ tional solidification of colloidal suspensions. First, models based on the purely statistical ⁵⁶² mechanical behavior of colloidal *solutions*, while a reasonable and necessary starting point, are likely not adequate to completely explain the phenomena observed during solidification. 563 That is, the densification that occurs as the solutions freeze is not analogous to that result-564 ing from simply increasing the density of particles in a colloidal fluid. Second, the results 565 add experimental evidence to the common assumption that the colloidal particles close pack 566 upon rejection from the solidification front and suggest that the packing achieved may be 567 the densest possible amorphous packing that can be produced given the particles' distribu-568 569 tion of sizes. Furthermore, the high particle density regions appear to be compact (i.e., not fractal) on the scale of several particle diameters. Finally, the observation of particle ag-570 gregates whose attractive van der Waal's interaction is sufficient to maintain their integrity 571 572 after melting suggests the possibility of creating macroscopic freeze-cast materials without ⁵⁷³ the need for special binding or sintering techniques.

In addition, our results may be useful in understanding other systems involving driven, ⁵⁷⁵ high concentration colloidal suspensions. They suggest that the arrangement of particles ⁵⁷⁶ at the smallest scales may not conform to predictions based solely on the interparticle in-⁵⁷⁷ teractions. Such differences could potentially influence the flow properties of the material ⁵⁷⁸ or dynamic behavior of the particles, which are of interest scientifically and for engineering ⁵⁷⁹ applications. Further study of the structure factor could incorporate hydrodynamic interac-⁵⁸⁰ tions between the particles and the effects of the driving force (such as repulsion from the ⁵⁸¹ ice), as has been done for the well characterized shear flow geometry [64]. Extending such ⁵⁸² work to more complicated forcing configurations and flow geometries is important because ⁵⁸³ these types of situations are often encountered in practical applications. Overall, solidified ⁵⁸⁴ colloidal suspensions are a promising system in which to study the effects of external driving ⁵⁸⁵ on particle arrangement because the particle-scale structure is effectively "frozen in" both ⁵⁸⁶ by the constraint of the surrounding ice and the strong van der Waal's attraction between ⁵⁸⁷ the particles.

588 V. CONCLUSION

We have presented a joint small angle x-ray scattering and direct imaging study of frozen 580 colloidal suspensions. Our results highlight the utility of these methods for studying the 590 ⁵⁹¹ structure of such materials and suggest routes for future investigation. By consulting the images acquired directly in laboratory freezing experiments, we identified the main peak 592 exhibited by the scattered x-ray intensity from frozen solutions as resulting from the close 593 packing of particles in high-particle-density regions formed between ice dendrites. The 594 enhanced intensity at low scattering vectors we attributed to the size of the high density regions. In addition, the close packing of the particles produced by freezing allowed the shortrange attractive inter-particle interaction to dominate thereby creating long-lived particle 597 aggregates. However, we found that the structure observed in our samples when they were 598 frozen could not be described by any of the standard inter-particle potentials even though 599 the unfrozen solutions were well-described by a hard sphere interaction with an effective hard 600 ₆₀₁ sphere radius. This implies that the process of freezing produces atypical arrangements of 602 the colloidal particles.

Further work could help clarify some of the issues encountered and expand upon the present conclusions. Importantly, by altering the solidification conditions, more controlled freezing could be attained and particle structure (including volume fraction) ahead of a solidification front (planar or dendritic/cellular) could be studied. By using a linear solidification geometry, as opposed to the radial geometry in the present experiments, we could better connect our observations with the original work on directional solidification of particle suspensions [66, 67]. Examining samples with a variety of higher and lower initial volume fractions would help determine the robustness of the close packed arrangement. Similarly, $_{611}$ using different sizes or types of particles would also contribute to answering this question. $_{612}$ Different size particles would shift the qR range accessed by SAXS and hence the scale of $_{613}$ the structures investigated with respect to the particle size. Different types of particles with $_{614}$ a more monodisperse size distribution would interact differently with each other, possibly $_{615}$ conforming more closely to one of the standard inter-particle potentials, which would either $_{616}$ allow more accurate modelling of the frozen structure or confirm that the freezing process $_{617}$ imposes a unique structure among the particles. Alternately, to focus on the structural $_{618}$ evolution over time, experiments could be performed in which the temperature was held $_{619}$ constant.

Finally, three other x-ray scattering techniques can provide complementary information 620 621 about the samples and should be utilized for studying solidifying colloidal suspensions. ⁶²² First, dynamic x-ray scattering, or x-ray photon correlation spectroscopy (XPCS), allows for determination of how the particles are moving, such as distinguishing between diffusive 623 and ballistic motion and measuring the rate of this motion. We have applied XPCS to 624 examine particles in frozen samples and present those results elsewhere [34]. A second 625 technique is x-ray near field scattering (XNFS), which combines aspects of x-ray scattering 626 ₆₂₇ and radiography, and also provides structural and dynamic information, though the analysis of the data is more complicated than in SAXS or XPCS [68]. However, XNFS has the benefits 628 of accessing smaller wavevectors than SAXS and permitting observation during freezing. 629 Third, ultra-small angle x-ray scattering (USAXS) can also access smaller wavevectors, but 630 with a data analysis procedure similar to that for standard SAXS [69]. USAXS could 631 clarify the structure at intermediate length scales and possibly identify the length scale associated with the low-q intensity upturn seen in our experiments. By combining SAXS 633 and other x-ray techniques future work will greatly increase our knowledge of the small 634 635 scale structure resulting from solidification of colloidal suspensions, which in turn will help 636 enhance understanding of the processes occurring during solidification and allow for better 637 control of the final solidified product.

649 Appendix: X-ray Scattering Background

For optically opaque materials, x-ray scattering can provide information about the struc-650 ture at length scales on the order of several to around 1000 nm. Small Angle x-ray Scattering 651 (SAXS) probes variations in the density of electrons in a material (usually analogous to the mass density), so in colloidal suspensions SAXS data reflect the density variations associated with the size of the colloidal particles and the predominant inter-particle spacings 654 [70]. However, these density variations are disclosed in reciprocal, or Fourier, space and a 655 model is needed to interpret the experimental results in terms of actual structure. At the 656 most basic level though, scattering vectors (or wavevectors) with higher scattered intensity 657 ⁶⁵⁸ indicate structure existing within the sample on length scales proportional to the inverse of ⁶⁵⁹ those scattering vectors. In this way, SAXS provides structural information about complex 660 materials.

The primary result of SAXS is the scattered intensity $I(\mathbf{q})$, where the scattering vector $_{662}$ \mathbf{q} is the vector difference between the wavevectors of the incident and the scattered x- $_{663}$ rays. It has magnitude q given by $4\pi/\lambda \sin(\Theta/2)$ (Θ is the angle between the incident and $_{664}$ scattered radiation) [70]. Frequently in experiments on colloidal suspensions the scattering $_{665}$ is expected to be isotropic, so analysis solely in terms of the magnitude of the scattering $_{666}$ vector is acceptable. The intensity as a function of q for identical particles can be expressed $_{667}$ AS

$$I(q) = \Phi_i E_{det} \Delta \Omega A_{det} d Tr \phi V_{part} (\Delta \rho)^2 P(q) S(q)$$
(A.1)

⁶⁶⁸ where Φ_i is the incident x-ray flux, E_{det} is the detector efficiency, $\Delta\Omega$ is the solid angle ⁶⁶⁹ subtended by the detector, A_{det} is the area of the detector, d is the sample thickness, Tr is ⁶⁷⁰ the transmission coefficient, ϕ is the particle volume fraction, V_{part} is the volume of a single ⁶⁷¹ particle, $\Delta \rho$ is the electron density contrast between the particles and the solvent, P(q) is ⁶⁷² the form factor, and S(q) is the structure factor [70, 71]. All information about the sample ⁶⁷³ structure is contained within P(q) and S(q).

The form factor P(q) describes the scattering from particles of a given size and shape. It can be calculated based on the distribution of mass within the particles for a variety of shapes (c.f. reference [41]). The structure factor S(q) describes the scattering from spatial correlations among the particle positions [72]. It is the Fourier transform of the radial distribution function, which describes the probability of finding two particles separated by a given distance. Theoretical estimates of structure factors typically rely on radial distribution functions derived for a specified inter-particle interaction, usually pair potentials such as hard spheres or a square well (c.f. reference [41]).

For systems without an a priori model, SAXS data still provide useful information. As the Fourier transform of the mass distribution within the sample, peaks in SAXS data correspond to structures on length scales of roughly $2\pi/q_{peak}$ [70, 73]. The peak width is related to the variation of this length scale around the primary one with wider peaks corresponding to greater variation. In terms of the particles' radial distribution function, the position of the primary peak in S(q) represents the average distance to a particle's nearest neighbors and the height represents the average number of neighbors. Thus, SAXS provides a way to probe the structure of complex, optically opaque materials.
