We observe dark and bright intrinsic localized modes (ILMs), also known as discrete breathers, experimentally and numerically in a diatomic-like electrical lattice. The generation of dark ILMs by driving a dissipative lattice with spatially-homogenous amplitude is, to our knowledge, unprecedented. In addition, the experimental manifestation of bright breathers within the bandgap is also novel in this system. In experimental measurements the dark modes appear just below the bottom of the top branch in frequency. As the frequency is then lowered further into the band-gap, the dark ILMs persist, until the nonlinear localization pattern reverses and bright ILMs appear on top of the finite background. Deep into the bandgap, only a single bright structure survives in a lattice of 32 nodes. The vicinity of the bottom band also features bright and dark self-localized excitations. These results pave the way for a more systematic study of dark breathers (DB) and their bifurcations in diatomic-like chains.

I. INTRODUCTION

The study of intrinsic localized modes (ILMs) was arguably initiated by the works of [1, 2] on the so-called Fermi-Pasta-Ulam-Tsingou lattices. It was subsequently significantly propelled forward by the rigorous proof of their existence in a large class of models starting from the uncoupled, so-called anti-continuous limit [3]. Since then, there has been a wide variety of systems in which experimental observations of structures have been reported that are exponentially localized in space and periodic in time. Among them, one can note arrays of Josephson junctions [4, 5], mechanical [6, 7] and magnetic pendula [8], microcantilevers [9], electrical chains [10, 11], granular crystals, [12, 13], ionic crystals such as PtCl [14] and antiferromagnets [15]. Moreover, these types of structures have been offered as plausible explanations of experimental findings in settings such as the DNA denaturation [16], α-uranium [17] or NaI [18]. For relevant reviews of ILMs, see, e.g., [19–21], as well as the more specialized works regarding optical [22] and solid state physics [24] applications and books such as [25].

A significant playground for the exploration of ILMs, since early on, has been offered by the setting of electrical lattices [26]. Progressively, over the last decade, these lattices have enjoyed a larger degree of control of their external drive and lattice configurations (one- vs. two-dimensional, nearest-vs. beyond nearest-neighbor configurations, etc.) [10, 27–29]. In these works, a qualitatively and semi-quantitatively accurate model of the dynamics has also been put forth. Building on this existing experimental, theoretical and computational background, we now advance a diatomic-like electrical lattice model.

More specifically, we construct a coupled-resonator circuit where one of the inductive elements alternates between two values for adjacent nodes, endowing the lattice with a diatomic structure. Such electrical lattices have been proposed (and even experimentally explored) since the early days of localized dynamics; see, e.g., [30]. Here, however, we explore some features not previously discussed, to the best of our knowledge. After confirming the linear two-band spectrum, we search the bandgap for the existence of nonlinear excitations. Both in the experiment and in the numerical simulations of the model, we identify breather structures consisting of density dips in a finite background, namely the so-called dark breathers (DBs). To the best of our knowledge, such DBs have previously been induced experimentally only in granular crystals [13], on the basis of earlier theoretical predictions in Hamiltonian and dissipative lattices, such as [31, 32]. Nevertheless, the latter setting only affords control of the driving boundaries, while no drive or spatio-temporal controls are available within the chain, as is the case herein. Hence, it can be argued that the present setting is far more amenable to the controllable generation and persistence of these states. DBs are found in the vicinity of the top band and, as we drive deeper in the spectral gap, the nonlinear states sustain a fundamental change of character and become bright ones, on top of the finite background (which previously supported the DBs). In addition, we have found that below the bottom band the system features dark and bright ILMs structures as well. To the best of our knowledge such features are unprecedented in electrical chains or, for that matter, in experimentally tractable nonlinear dynamical lattices generally.

Our presentation is structured as follows. First, we present
the experimental setup and corresponding theoretical model. We then discuss our results for both dark and bright ILMs. Finally, we summarize our findings and present some directions for future study.

II. EXPERIMENTAL AND THEORETICAL SETUP

In our electrical lattice, the connected nodes are RLC resonators comprised of inductors $L_2^{(a,b)}$ and varactor diodes providing a voltage-dependent, nonlinear capacitance, $C(V)$. In order to make this lattice a diatomic system, we have incorporated two different cells, (a) and (b), with different values of inductors, $L_2^{(a)}$ and $L_2^{(b)}$, located on alternate sites. Thus, the unit cell is the node-pair, and each node of one type is surrounded by two nodes of the other type. Neighboring nodes are coupled inductively via inductors, $L_1$, and driven by a sinusoidal signal via a resistor, $R$. We also connect the last circuit cell to the first, thus implementing periodic boundary conditions.

The sinusoidal driver is spatially homogeneous in amplitude, but staggered in space from one unit cell to the next. This drive was provided by an Agilent 33220A function generator, which for half the nodes was inverted using a fast operational amplifier (LF411). The integrity of the signals was checked with an oscilloscope. This means that we instituted a phase shift of $\pi$ between two consecutive nodes of the same type, so that the zone boundary plane-wave modes could be excited. (The two sites within a given unit cell were driven in phase.) We denote the driver amplitude by $V_d$, and its angular frequency by $\omega_d$. A sketch of the system is shown in Fig. 1.

![FIG. 1: (a) Schematic circuit diagrams of the electrical lattice, where the blank points represents circuit cells of type (a) and black points represent circuit cells of type (b). Black arrows represent driving and its phase. (b) Each cell is connected to a periodic voltage source $V_s(t)$ via a resistor $R$, and grounded. Each point $A$ of an elemental circuit is connected via inductors $L_1$ to the corresponding points $A$ of neighboring cell. Voltages are monitored at point $A$.](image)

Furthermore, the concrete parameter values of the system (comprised of inductors, resistors and capacitors) are $L_1 = 0.68 \, \text{mH}$, $L_2^{(a)} = 102.7 \, \mu\text{H}$, $L_2^{(b)} = 970 \, \mu\text{H}$, $R = 10 \, \text{k\Omega}$ and a NTE 618 varactor, for which the capacitance at zero voltage is $C_0 = 770 \, \text{pF}$. The number of nodes of each type was $N^{(a)} = N^{(b)} = 16$, equating 16 unit cells for a total of 32 nodes. Experimentally, node voltages $V_n$ at points $A$ were measured at a rate of 2.5 MHz using a 32-channel analog-to-digital converter. In order to obtain a higher-resolution picture of the nonlinear localized modes, the full time-series experimental data (of around 100 driver periods) can be folded back into a single period using knowledge of the precise temporal periodicity (i.e., frequency). These higher-resolution pictures also compare very well to traces independently taken at individual nodes with a 1 GS/s oscilloscope.

We should note that a macroscopic lattice can never be made exactly homogeneous from node to node, but the inhomogeneity in our electrical lattice is small. More precisely, all inductors used bear inductances to within one percent of one another, and the varactor diodes have a standard deviation in their measured capacitance of about 3 percent. Their exact nonlinear response cannot be captured by a single number, of course, but we would expect these pn-junctions to behave very much alike. The relative insignificance of the lattice inhomogeneity can be demonstrated by observing that ILMs can be created anywhere in the lattice.

It has been shown that the basic dynamics of this electrical network can be qualitatively described by a simple model where the introduction of an amplitude-dependent phenomenological resistor, $R_l$, in parallel to the cell capacitance, is enough to reproduce experimentally observed features quite well [10]. Accordingly, the dimensionless equations of motion read

$$\frac{di_n}{d\tau} = \frac{L_2^{(a)}}{L_1}(v_{n+1} + v_{n-1} - 2v_n) - \frac{L_2^{(a)}}{L_2^{(b)}}v_n$$

$$\frac{dv_n}{d\tau} = \frac{1}{c(v_n)} \left[ i_n - id + \cos(\Omega \tau) - \frac{v_n}{\omega_0 RC_0} - \frac{v_n}{\omega_0 R_C C_0} \right],$$

where $L_2^{(n)} = L_2^{(a)}$ if site $(n)$ corresponds to nodes (a), or $L_2^{(n)} = L_2^{(b)}$ if it corresponds to nodes (b). The following dimensionless variables have been used: $\tau = \omega_0 t; i_n = (I_v - I_d)/(\omega_0 C_0 V_d)$, where $I_v$ is the full current through the unit cell and $I_d$ is the current through the inductor $L_2^{(n)}$, both corresponding to cell $n; v_n = V_n/V_d$. Here, $V_d$ is the driver amplitude, and $V_n$ is the measured voltage at node $n$; $\Omega = \omega_d/\omega_0, \omega_0 = 1/\sqrt{L_2^{(a)} C_0}, i_d = I_D/(\omega_0 C_0 V_d)$, where $I_D$ is the current through the varactor diode; $c = C(V)/C_0$, and $C(V)$ is the nonlinear capacitance of the diode. $R_c$ is the equivalent resistance so $1/R_c = 1/R + 1/R_l$.

The main loss/decay channels in this experimental system are the varactor diodes during the negative voltage swings (forward bias) due to resistive current flow and recombination effects. In addition to this on-site dissipative channel, the coupling inductors also have some series resistance which gives rise to a small inter-site resistance. The model ignores these details in favor of only one phenomenological term, $R_l$.

Numerically we have calculated discrete breathers as spatially localized periodic solutions of Eq. (1). In order to study numerically its linear stability we have examined the evolution of a small perturbation of a given periodic solution to first order and performed a Floquet analysis. ILM stability is then determined by the Floquet multipliers so that if the coherent structure is stable, all of them lie inside the unit circle. [10, 33]
III. RESULTS AND DISCUSSION

In the limit of no driving and for small-amplitude oscillations the linear modes possess frequencies grouped into two bands, as expected on the basis of the diatomic structure of the lattice. The top (optic-like) and bottom (acoustic-like) bands of the linear spectrum are found to lie within the intervals \([314 – 356]\) and \([645 – 666]\) kHz, respectively. A plot of the theoretical dispersion bands - obtained from linearizing Eq. (1) - is shown in Fig. 2, and the linear modes corresponding to top and bottom of the two bands are shown in Fig. 3. Using the spatial signature of the driving outlined before, we are able to experimentally excite and pump the linear mode of Fig. 3(c) and (b), and we proceed to explore the dynamics of such a mode for frequencies within the bandgap (i.e., in the regime of nonlinear, breather-like excitations [20]).

![Fig. 2](image)

**FIG. 2:** (a) Electrical line linear mode frequencies \(f\) as function of the wavevector \(q = n\pi/N\), where \(n = -N/2 \ldots N/2\) and \(N = N(a) + N(b)\). A solid line is used to denote the top and a dashed to denote the bottom band. Figures (b) and (c) show the ratios between different linear mode amplitudes in the bands, where \(A\) correspond to oscillation amplitudes of cells of type \((a)\) and \(B\) to cells of type \((b)\).

A. Dark gap breathers

The existence of bright ILMs below the lower linear dispersion band has been well established in such systems, driven either directly or with a subharmonic driver [10, 27–29]. In this work, we focus on the existence and properties of ILMs in the band-gap, where we have, remarkably, found both dark and bright breathers (with non-vanishing background), depending on the precise driver frequency within the gap.

Figure 4 shows the experimental result for driving at a frequency of 571 kHz, about 25% into the gap from above, and 74 kHz below the lower band-edge of the top band (the zone-boundary mode is at 645 kHz). The amplitude is \(V_d = 3.5\) volts. The lattice profile of maximum and minimum node voltages in Fig. 4 clearly indicates the presence of a dark localized mode located around nodes 16 and 17. The term “dark” is used to describe a localized mode for which the amplitude of oscillation is large and constant in the lattice except at the ILM center and in its close vicinity (where it is near vanishing). Such structures, although theoretically proposed early on in [32], were only identified quite recently in a materials system (a granular crystal) in the work of [12]. There, they were produced as a result of the destructive interference of waves emanating from the boundary, while here they are robustly created by the drive within the bandgap, as evidenced in the computational stability analysis of Fig. 4. Figure 5 shows the experimental time series at selected nodes. On one sublattice, node 17 (red dots) is suppressed relative to node 15 (blue diamonds), and on the other sublattice, node 16 (black, open circle) is suppressed relative to nodes 14 (green crosses) and 18 (yellow pluses). Experimentally (left panel), we see that the amplitude on the large-oscillation sublattice is reduced at the dark ILM center to about half the value in the wings. Numerically (right panel) the reduction is similarly (or even more) pronounced for these particular driving conditions.

In other experimental runs, the center of the dark ILM

**FIG. 4:** (a) Numerical (dotted line) and experimental (circles) DB profile (maximum and minimum amplitude) corresponding to \(V_d = 3.5\) volts and \(f = 571\) kHz. Blank points represent circuit cells of type \((a)\) and black points represent circuit cells of type \((b)\). (b) Floquet multiplier numerical linearization spectrum confirming that, since all multipliers are inside the unit circle, the stability of the solution

![Diagram](image)
forms at different locations within the lattice, so this is not an impurity effect and as expected in a longer (nearly) homogeneous lattice the DB enjoys the discrete shift invariance of the diatomic chain. Nevertheless, we also observe that the location can be predetermined (i.e., designed) by placing a temporary impurity at the chosen site before turning on the driver. The sign of the impurity necessary to seed a dark ILM is opposite to the one needed for bright ILMs. Numerically, we find stable one–peak DBs existing in the range of $[569.5\text{--}600]$ kHz for a drive amplitude of $V_d = 3.5$ volts. It remains an important, albeit numerically rather demanding, question as to whether the DB can be found in computations throughout the system’s bandgap.

Decreasing the driving frequency further into the bandgap, a pattern of multi-peak dark ILMs emerges, as shown in Fig. 6. The number of dark ILMs in the lattice is very sensitive to the precise driver frequency at constant amplitude. In general, decreasing the driving frequency produces multi-peak structures and numerical solutions show overall good agreement with experimental results. However, numerics and experiments differ as to the precise localization centers, and in experiments they are found to be spaced somewhat more closely than in the numerical results. Nevertheless, the numerical results strongly suggest that such coherent structures should be dynamically robust, in line with the corresponding experimental observations. As also seen in previous studies, where the ILM is generated by a uniform driver, it can be sensitive to small lattice impurities which are, unfortunately, hard to completely eliminate in a manufactured lattice.

### B. Bright gap breathers

As we have seen, upon lowering the frequency, the DBs persist and apparently the number of their stable dips is increased within the chain. It is interesting that this is analogous to the phenomenology observed in the granular case, as discussed in [12]. Nevertheless, as the frequency is further reduced, an unprecedented (to our knowledge) scenario develops. More specifically, the localized pattern inverts, i.e., an excited set of nodes appears above the background value. Thus, a train of bright localized modes appears. If the frequency is further lowered within the gap, the peaks within this multi-peak pat-
Figure 8: (a) Numerical (dotted line) and experimental (circles) one-peak bright breather profile (maximum and minimum amplitude) corresponding to $V_2 = 3.5$ volts and $f = 528$ kHz. Blank points represent circuit cells of type (a) and black points represent circuit cells of type (b). (b) Floquet multiplier numerical linearization spectrum confirming, similarly as above, the stability of the solution.

Figure 9: Summary of the progression from dark to bright multi-peak ILM structures. Panels (a) show the driver frequency as a function of the number of breathers, both dark (circles, red) and bright (squares, blue). At around 550 kHz, we observe an equal mixture of bright and dark breathers. (b) - (d) show the experimental data corresponding to select frequencies.

The vicinity of the bottom band also features bright and dark ILMs. Figure 10 depicts the situation at a driver frequency of 280 kHz, just below the bottom of the band. One DB is clearly visible at site $n=13$ in the experimental data. Simulations also find this DB, although the background amplitude is slightly higher than in the experiment under identical driving conditions. Floquet analysis again shows that this mode is dynamically stable; see Fig. 10(b).

If the driving frequency is lowered by a mere 10 kHz to 270 kHz, bright ILMs are generated. These bright ILMs just below the bottom band are different from the bright ILMs of the top band in that their localization centers are on the opposite sublattice, namely the sublattice of $L_2$ sites characterized by the larger inductance value. The situation is succinctly depicted in Fig. 11 where so-called frequency shift key modulation (FSK) is employed to switch the driver frequency abruptly from one value to another. Here a shift from 271 kHz to 543 kHz was initiated in the experiment at a time of 2000 µs. The first frequency is consistent with two bright breathers with the associated (lower) frequency, whereas the second generates two bright breathers with the corresponding (higher) frequency in a different location. We see that the breathers are initially located on even sites, but after 2000 µs quickly settle on odd sites. The FSK technique can also be used to switch between
FIG. 10: (a) Numerical (dotted line) and experimental (circles) DB profile (maximum and minimum amplitude) corresponding to $V_d = 3.5$ volts and $f = 280$ kHz. Blank points represent circuit cells of type (a) and black points represent circuit cells of type (b). (b) Floquet multiplier numerical linearization spectrum confirming the stability of the solution.

bright and dark breathers within the upper band, by selecting two appropriate drive frequencies, such as 565 kHz and 535 kHz.

FIG. 11: Experimental FSK modulation that switches abruptly between two distinct values of the driving frequency while keeping the amplitude fixed at 3.5 V. Initially, for $f = 271$ kHz, two breathers are seen, but then when the frequency switches to 543 kHz, two distinct ILMs at a different location with the latter frequency (centered on odd sites) develop.

IV. CONCLUSIONS & FUTURE WORK

In the present work, we have examined the setting of electrical lattices in the form of a controllable/tunable diatomic-like system. Building on the modeling successfully used earlier for the monatomic case, we have considered both the linear and especially the nonlinear properties of this system, examining them in parallel both at the experimental and numerical level. We have found these lattices to be very useful playgrounds for the exploration of dark breather and multi-breather structures. Such states have spontaneously emerged in the experiments at different frequencies within the bandgap near the top band. However, as one further lowers the frequency, a bright nonlinear structure (on top of a background) emerged, involving initially multiple peaks, which then become progressively fewer (as the frequency was further lowered), before eventually disappearing altogether well above the cutoff frequency of the bottom band.

While the structures reported here, we feel, are intriguing, they also pose numerous open questions for future consideration. Many of these can be addressed by a systematic analysis of the bifurcations of single and multiple dark and bright breathers in the bandgap. Such an analysis, while computationally demanding, would offer a more systematic roadmap for future experiments. There we could explore what happens in the immediate vicinity of the (upper edge of the) bottom branch, as well as the (lower edge of the) top branch. Extensions of these fairly controllable structures would also be worthwhile to consider in higher dimensional systems. Some of these questions are currently under consideration and will be reported in future publications.
