We realize a two-dimensional kagomé lattice for ultracold atoms by overlaying two commensurate triangular optical lattices generated by light at the wavelengths of 532 nm and 1064 nm. Stabilizing and tuning the relative position of the two lattices, we explore different lattice geometries including a kagomé, a one-dimensional stripe, and a decorated triangular lattice. We characterize these geometries using Kapitza-Dirac diffraction and by analyzing the Bloch-state composition of a superfluid released suddenly from the lattice. The Bloch-state analysis also allows us to determine the ground-state distribution within the superlattice unit cell. The lattices implemented in this work offer a near-ideal realization of a paradigmatic model of many-body quantum physics, which can serve as a platform for future studies of geometric frustration.

PACS numbers:

Geometrically frustrated systems with a large degeneracy of low energy states are of central interest in condensed-matter physics\cite{1,2}. The kagomé net – a pattern of corner-sharing triangular plaquettes – presents a particularly high degree of frustration. Such frustration impacts the kagomé quantum antiferromagnet, for which the ground state, proposed to be a quantum spin liquid or valence bond solid\cite{3–10}, remains uncertain despite decades of work. Resolving such uncertainty by experiments on solid-state kagomé magnets\cite{11,12} is complicated by the significant magnetic disorder or anisotropy of such materials. For this reason, more faithful realizations of quantum many-body physics in the kagomé lattice are needed.

Ultracold atoms trapped within optical lattices offer clean realizations of exotic phases of matter in condensed-matter physics\cite{13}. Recently, non-primitive optical lattices with multiple lattice sites per unit cell have been realized in the honeycomb\cite{14} and checkerboard\cite{15} geometries, and double-well superlattices\cite{16,17}, revealing non-trivial ordering and dynamics arising from a low-energy orbital degree of freedom\cite{18}. The kagomé lattice with ultracold atoms has attracted significant interest in this context as well\cite{19,20}, but it has not been experimentally demonstrated to our knowledge.

In this Letter, we present the realization of the kagomé geometry in a two-dimensional optical superlattice for ultracold $^{87}$Rb atoms. The kagomé lattice is obtained by eliminating every fourth site from a triangular lattice of spacing $a/2$, with the eliminated sites forming a triangular lattice of spacing $a$. The remaining sites generate three connected s-orbital bands within a bandwidth on the order of the intersite tunneling energy. Intriguingly, the frustration besetting antiferromagnetic interactions also implies that one of these bands be non-dispersing. Such flat bands, distinguishing the kagomé configuration from non-primitive lattices\cite{14–17}, accentuate the role of interparticle interactions, leading possibly to crystalline ordering\cite{21} and supersolidity\cite{22} for scalar bosons, and ferromagnetism of itinerant fermions\cite{23}. Furthermore, geometric frustration of the kagomé lattice shows macroscopic degeneracy of lowest-energy classical states with XY-type antiferromagnetic interactions in contrast to the triangular lattice\cite{24}. Our work therefore opens the door to investigations of how geometric frustration affects both orbital and magnetic properties of materials.

Our kagomé lattice is formed by overlaying short-wavelength (SW) and long-wavelength (LW) triangular lattices, formed with light at the commensurate wavelengths of 532 nm and 1064 nm, respectively\cite{25}. In a single-wavelength lattice, formed by three plane waves of light of equal intensity $I$ and wavevectors (and linear polarizations) lying in a plane and intersecting at equal angles, one obtains a triangular lattice of points with zero intensity, and a honeycomb lattice of points with maximum intensity $\frac{3}{4}I$ separated by a triangular lattice of intensity saddle points with intensity $\frac{1}{4}I$. Our SW light lattice is blue-detuned from the principal atomic resonances of rubidium, so that atoms are attracted to the triangular lattice of zero-intensity sites with a lattice spacing of $a/2 = (2/3) \times 532 \text{nm} = 355 \text{nm}$. The LW lattice is red-detuned, so that its zero-intensity points are potential-energy maxima for rubidium atoms. A unit cell of the LW lattice contains four sites of the SW triangular lattice, labeled A, B, C and D in Fig. 1. Aligning the positions of the LW potential maxima to coincide with sites D lowers the potential energies $V_{A,B,C}$ at the other sites by equal amounts $\Delta V = V_D - V_{A,B,C} = \frac{5}{9} V_{LW}$ where $V_{LW}$ is the maximum scalar potential depth of the LW lattice (we ignore the ~1% vector shift in this lattice\cite{26}). As $\Delta V$ is increased, atoms are excluded from sites D, while the remaining sites form the kagomé optical lattice. The kagomé geometry persists until $V_{LW} > 9 V_{SW}$, at which point atoms become preferentially confined in
the LW honeycomb lattice.

Compared to previous proposals [19, 20], our simpler approach to creating a kagomé lattice allows one to tune the lattice geometry, thereby controlling its degree of frustration. Aligning the LW potential maxima with the SW lattice saddle points disfavors population in two sites of the four-site unit cell (e.g. \(V_{B,C} < V_{A,D}\)) producing a one-dimensional (1D) stripe lattice (Fig. 1c or Fig. 3a). Aligning the LW potential maxima with the SW potential maxima disfavors population in three sites of the unit cell (e.g. \(V_{A,B,D} > V_{C}\)), producing a decorated triangular lattice with lowest-energy sites forming a triangular lattice while the remaining sites form a kagomé lattice of local potential minima.

Experiments were conducted with scalar Bose-Einstein condensates of \(\sim 3 \times 10^5\) \(^{87}\)Rb atoms produced at temperatures of 80 nK in a red-detuned crossed optical dipole trap with trap frequencies of \((\omega_x, \omega_y, \omega_z) = 2\pi \times (60, 30, 350)\) Hz, with \(\omega_z\) applying vertically. The large \(\sim 100 \mu\)m beam-waist diameters of the lattice beams ensured that the lattice potential modified the trapping frequencies by less than 10%. Laser alignments and relative intensities were tuned to produce six-fold symmetric diffraction patterns of condensates released from LW- and SW-only lattices. The relative displacement of the LW and SW lattices was measured using two- and three-color Mach-Zehnder interferometers, one for beams 1 and 2 and the other for beams 1 and 3, and stabilized using piezo-actuated mirrors in the optical paths [27]. A tilted glass plate within each interferometer introduced a relative shift between the two lattice colors that, following stabilization, was imparted onto the optical lattice.

We employed atom optics to characterize the lattice as it is tuned between various geometries. These atom-optical tools presented in this work may be useful for the characterization of other superlattices and for superlattice-based atom interferometry. The first of these tools is Kapitza-Dirac diffraction [28, 29], for which the momentum distribution should also be symmetric under inversion. Expansion from both the kagomé and the decorated triangular lattices shows the three-fold rotational symmetry of the optical superlattice. In the 1D stripe geometry, one expects equally weak occupation of two sites (e.g., A and D), and equally strong occupation of the other two sites (B and C) of the superlattice unit cell. Such a distribution is (nearly) invariant under displacements of \(a/2\) along the A-D axis, and condensate diffraction along that axis should reflect the shorter periodicity of the SW lattice. The momentum distribution should also be symmetric under reflection about the A-D axis. Both traits are observed experimentally.

The Bloch-state momentum distributions allow one to quantify the ground-state wavefunction within a unit cell of the superlattice, which we express as \(\psi(r) = \sum_\alpha \psi_\alpha w_\alpha(r - s_\alpha)\) where \(w_\alpha(r)\) is the normalized Wannier state wavefunction, \(s_\alpha\) the position and \(|\psi_\alpha|^2\) the fractional atomic population of site \(\alpha \in \{A, B, C, D\}\) of the unit cell. At low \(V_{LW}/V_{SW}\), we approximate \(w_\alpha = w\) as cylindrically symmetric, Gaussian, and identical for all \(\alpha\). From the momentum-space populations \(P_{G_i}(i \in \{1, 2, 3\})\) in the three first-order diffraction peaks of the LW lattice [30]—corresponding to the inner hexagon of peaks in time-of-flight images—and that at zero wavevector \(P_0\), one determines the distinct quantities

\[
\bar{P}_i = \frac{P_{G_i} + P_{-G_i}}{2P_0} \frac{|\bar{w}(0)|^2}{|\bar{w}(G_i)|^2} = \frac{|\psi_\beta + \psi_\gamma - \psi_\delta - \psi_\epsilon|^2}{|\sum_\alpha \psi_\alpha|^2}
\]

where \(\psi_\alpha\) and \(\bar{w}(G_i)\) are now Fourier components of the Wannier function, and \(\beta, \gamma, \delta\) and \(\epsilon\) label the four
sites so that $G_{\alpha} \cdot (s_{\beta} - s_{\alpha}) = 0$. The Wannier state Fourier components in Eq. 2 are determined from the second-order diffraction populations as $|\tilde{w}(0)|^2 / |\tilde{w}(G_{\alpha})|^2 = (2P_0/(P_{2G_{\alpha}} + P_{-2G_{\alpha}}))^{1/4}$. Together with the normalization $\sum_{\alpha} |\tilde{v}_{\alpha}|^2 = 1$ these quantities determine the atomic distribution in the unit cell [31].

We measured the population ratios $P_i$ as the superlattice geometry was gradually tuned. Translating the relative position of the two lattices (Fig. 3b), one advances from the kagomé geometry, with equal population in the three ratios, to the 1D stripe geometry, with two identically small ratios, and then to another kagomé-geometry lattice. Our data agree with a calculation of the single-particle ground-state for the known lattice depths.

We focus finally on the kagomé-geometry lattice alignment, and examine the transition between the triangular and kagomé geometries (Fig. 4). At zero $V_{\text{LW}}$, the atoms are confined in a SW triangular lattice, and the first-order LW lattice diffraction orders are absent, indicating a unit-cell population of $(A, B, C, D) = (1/4, 1/4, 1/4, 1/4)$. As the LW lattice depth is increased, the population ratios $P_i$ increase and the kagomé geometry is achieved by gradually expelling atoms from one site of the unit cell. The population ratios tend toward a limiting value of $1/9$ that is a hallmark of diffraction from a kagomé lattice wherein the atoms are distributed as $(A, B, C, D) = (1/3, 1/3, 1/3, 0)$.

Here, the ground state of the kagomé lattice does not suffer from frustration. In the future, effects of frustration may be explored by transferring bosons into the excited s-orbital flat band, or by changing the sign of the hopping energy [32] so that the flat band becomes the lowest in energy. The present choice of wavelengths also yields kagomé lattices for the fermionic isotopes $^6\text{Li}$ and $^{40}\text{K}$. Introducing fermions into the lattice at the appropriate fillings would place the Fermi energy within the flat band, allowing for studies of flat-band ferromagnetism due to repulsive interactions [23] or enhanced Cooper pairing for attractive interactions [33]. Also, the demonstrated tunability of the superlattice opens new possibilities to emulate both ideal and deliberately distorted kagomé lattices, potentially stabilizing the various candidate ground states of the kagomé quantum antiferro-
FIG. 3: The real- and momentum-space composition of a superfluid for various lattices. (a) The kagomé and decorated triangular lattices maintain three-fold rotational symmetry in configuration and momentum space, while the symmetry of the 1D stripe lattice is reduced to a parity symmetry (left-right in the images). For each setting, a schematic distinguishes between sites of high (green) and low (red) atomic population. The expected momentum distribution for measured values of $V_{SW}/h = 40 \text{kHz}$ and $\Delta V/h = 14 \text{kHz}$ is shown with the area of the black dot reflecting the fractional population. (b) Translating the LW-lattice potential maxima (marked as a star in the schematic) along the A-D axis tunes the lattice between kagomé and 1D stripe geometries, as revealed by the population ratios $P_i$ identified according to the inset. The data (averages of 4-5 measurements) agree with calculations of the single-particle ground state (solid lines) with the lattice depth used in the experiment. Interaction effects are neglected since $\Delta V$ was higher than the chemical potential $\mu/h \sim 3.5 \text{ kHz}$.

FIG. 4: The superlattice was converted from a SW triangular to a kagomé lattice by increasing $V_{LW}$. As $\Delta V$ exceeds the condensate chemical potential ($\mu/h \simeq 3.5 \text{ kHz}$), (a) the momentum population ratios reach the asymptotic value of $1/9$ expected for a kagomé lattice, and (b) the D-site population is extinguished. Data points represent averages of 7-10 measurements. In (a), the dashed curve indicates the predicted $P_i$ while the shaded region indicates the expected variation in $P_i$ given a shot-to-shot instability of $\sim 20 \text{ nm}$ in the relative position of the LW and SW lattices.
[25] While the SW and LW wavelengths of 532.15 nm and 1063.96 nm are not perfectly commensurate, the relative displacement of the SW and LW lattices varies by only (18,9) nm over the ($d_x, d_y$) = (28,14)$\mu$m transverse diameter of the condensate.
[27] For Kaptiza-Dirac diffraction, stabilization was engaged with the lattice at negligible intensity before the brief high-intensity pulse. For Bloch-state analysis, stabilization was engaged upon the ramp-on of the lattice beams.
[30] Momentum populations of condensed atoms are measured by integrating under the narrow time-of-flight atomic distributions. The contribution from the thermal atoms is subtracted, thereby accounting for finite-size, finite-temperature, and interaction effects during the expansion of the gas.
[31] We assume that all atoms lie in the ground band of the lattice potential with constant phase. Inverting Eqs. 2 gives a discrete degeneracy of solutions that is resolved by knowledge of the approximate populations.
