We show results on the vortex core dissipation through current-voltage measurements under applied pressure and magnetic field in the superconducting phase of CeCoIn₅. We find that as soon as the system becomes superconducting, the vortex core resistivity increases sharply as the temperature and magnetic field decrease. The sharp increase in flux flow resistivity is due to quasiparticle scattering on critical antiferromagnetic fluctuations. The strength of magnetic fluctuations below the superconducting transition suggests that magnetism is complimentary to superconductivity and therefore must be considered in order to fully account for the low-temperature properties of CeCoIn₅.

PACS numbers: 71.10.Hf, 71.27.+a, 74.70.Tx

Unconventional superconductivity in heavy-fermion material CeCoIn₅ is a complex state of matter involving magnetic and conduction degrees of freedom strongly coupled with each other [1–5]. Superconductivity emerges at a temperature $T_c \simeq 2.3$ K with the order parameter most likely having d -wave symmetry [6–9]. The magnitude of the specific heat jump at the superconducting transition temperature [1, 10] indicates the mass enhancement of conduction electrons by several orders of magnitude. Normal state resistivity shows non-Fermi liquid linear temperature dependence at low temperatures (< 20 K). Approximately at a temperature $T^* \simeq 45$ K [1, 11], the heavy electrons begin to form due to the strong hybridization between the conduction electrons and localized Ce f -electrons. Despite the significant enhancement of the electronic mass, the magnetic susceptibility shows a Curie-Weiss behavior down to moderately low temperatures [1, 2, 12, 13] signaling the absence of the fully quenched magnetic moments.

The pronounced non-Fermi liquid behavior in the normal state and unconventional superconductivity in CeCoIn₅ are thought to arise from the proximity of the system to a quantum critical point (QCP) separating paramagnetic and antiferromagnetic phases. Specifically, it was recently proposed that the transport and thermodynamic properties of CeCoIn₅ in the normal phase are controlled by an antiferromagnetic QCP at an inaccessible negative pressure [14]. The recovery of a Fermi liquid state at low temperatures and high magnetic fields was reported in Ref. [15], pointing to a field-induced QCP at the zero-temperature upper critical field $H_{c2}(0)$. However, the location of the field-induced QCP exactly at $H_{c2}(0)$ seems to be just a coincidence, since, with increasing pressure, this QCP moves inside the superconducting dome to lower fields. In fact, high sensitivity Hall effect measurements have revealed that the field induced QCP is located at $H \simeq 4.1$ T $< H_{c2}(0)$, which suggest a possible antiferromagnetic ground state superseded by superconductivity [16]. In addition, low temperature thermal expansion data [17] on identification of the quantum critical line can be consistently interpreted within the same set of ideas as the Hall effect data. Thus, all these observations seem to favor the antiferromagnetic QCP scenario [18]. What is important for our discussion, however, is that all the experiments discussed above address the physics of the QCP and superconductivity by extrapolating results obtained in the normal state. Presently, there are no *direct* probes of antiferromagnetism and quantum criticality in the superconducting state.

This motivated us to study the transport in the mixed state: superconductivity inside the vortex core is suppressed, thus revealing the physics of antiferromagnetism and quantum criticality of an underlying normal state. In this Letter we present the results from directly probing the nature of the normal state and quantum criticality under the superconducting dome of CeCoIn₅ by measuring the vortex core dissipation through current-voltage (I - V) characteristics under applied hydrostatic pressure (P). We observe that the vortex core resistivity increases sharply with decreasing temperature (T) for $T < T_c$ and magnetic field (H). This behavior is greatly suppressed with increasing pressure, due to the suppressed antiferromagnetic (AF) order inside the vortex core. Using our experimental results, we obtain an explicit equation for the antiferromagnetic boundary inside the superconducting dome and construct an $H - T - P$ phase diagram, which provides direct evidence for a quantum critical line inside the superconducting phase. All these results show the close relationship between quantum criticality, antiferromagnetism, and superconductivity.

The electrical resistivity in the mixed state of type-II superconductors is related to the motion of Abrikosov vortices [19]. When the Lorentz force is larger than the pinning force, the flux lines are driven into a viscous-flow state. The flux-flow resistivity is defined as $\rho_{ff} \equiv kdV/dI$, where dV/dI is the slope of the linear region of the I - V curve and k is a geometric factor ($k = 0.11$ mm for the single crystal which data are presented here), and is dominated mainly by the quasiparticle scattering in the vortex core. The flux-flow resistivity is independent of the depinning current (I_c) of the sample (defined as the extrapolation of the linear I - V range to zero voltage) or of the pinning force. In other words, ρ_{ff} is a quantity that is determined only by the bulk properties of the material.

We plot the dependence of resistivity ρ (circles) and critical current I_c (stars) on H , applied along the c -axis, and T on left and right panels of Fig. 1, respectively. These dependences are extracted from the I - V curves (see supporting online materials for details). First notice that the critical current I_c increases sharply below a certain magnetic field, which we define as the upper critical field (H_{c2}) at the given temperature. When we decrease the value of the external magnetic field, the resistivity $\rho(H)$ first decreases to its minimum value around $H_{c2} \approx 1.25$ T (for $T = 2.25$ K) and then increases. This behavior in the mixed state is in sharp contrast with the well known linear relationship between ρ_{ff} and H for low H and the saturation of ρ_{ff} near H_{c2} for a moderately clean superconductor [20]. We also see that when we decrease the magnetic field even further, ρ_{ff} displays a sharp maximum at $H \simeq 0.026$ T. As discussed later, this maximum is most likely due to the transition from dynamic to static antiferromagnetic order. Note that, in order to get a benchmark for the vortex contribution to transport, we also measure directly (as opposed to ρ_{ff}) the resistivity at $T = 2.25$ K with $I = 1$ mA. Our results are shown in the top left panel of Fig. 1 (open squares). The normal-state data corresponding to the two measurements overlap within 4%. The difference between these two curves below H_{c2} is a result of the fact that the open circles measure the free flux-flow dissipation of the vortices while the open squares measure the dissipation of the vortices in the presence of pinning.

The right panels of Fig. 1 show, as expected, that the critical current I_c is close to zero at high T and it increases

sharply below $T = 2.1$ K, which we define as T_c for this particular value of $H = 2$ T. The resistivity is metallic in the normal state, displays a minimum at $T_c(2\text{ T}) \approx 2.1$ K, and it shows a fast increase with further decreasing T in the mixed state down to 1 K (see top right panel of Fig. 1 and its inset, and the online supplementary materials for details).

All these results show that the vortex core in the mixed state of CeCoIn₅ is non-metallic while the normal-state behavior (i.e. above T_c) is metallic. Moreover, we note that CeCoIn₅ is in the superclean regime only for zero or very low H values. Even magnetic fields of the order of 0.1 T dramatically reduce quasiparticle mean free path by an order of magnitude [21], which pushes CeCoIn₅ into the moderately clean limit. For moderately clean superconductors, the flux flow resistivity $\rho_{ff} \approx \rho_n$ when H is close to H_{c2} [20]. Thus, the upturn in ρ_{ff} in the mixed state reflects the increase in the scattering of the quasiparticles in the vortex core.

Generally, one would expect the scattering of the quasiparticles in the vortex core and normal state to be very similar to each other, as it happens in UPt₃ (see for example Ref. [20]) despite the fact that strong antiferromagnetic fluctuations are present in this latter system [22]. However, possible deviations from this behavior may occur due to the presence of several competing interactions. It has been shown that the linear temperature dependence of resistivity in the normal state of CeCoIn₅ is governed by the proximity of the system to an antiferromagnetic QCP [23]. In fact, subsequent experiments showed that CeCoIn₅ is, indeed, close to an antiferromagnetic instability: 0.75% Cd doping gives rise to antiferromagnetism in this system [24]. In addition, NMR measurements have shown the presence of long range AF order inside the vortex core below 290 mK [25]. Thus, we are lead to interpret the observed upturn in the flux-flow resistivity as being due to critical antiferromagnetic fluctuations in the vicinity of the boundary separating antiferromagnetic and paramagnetic phases, i.e. for temperatures near the Néel temperature (T_N) [26]. The fact that ρ_{ff} starts increasing just below the SC boundary (see top panels of Fig. 1) suggests that the dynamic AF order emerges at the SC phase boundary, but that the static AF order appears at lower H and T , since critical spin fluctuations, which induce the enhancement of resistivity, disappear when the static AF order develops. Hence, our results suggest that the system releases the magnetic entropy from the unquenched magnetic moments in the superconducting state and antiferromagnetism becomes complimentary to superconductivity in CeCoIn₅.

Our interpretation is supported by the recent observation of the upturn in resistivity in CeCoIn_{1-x}Cd_x ($x=0.75\%$) close to the onset of the AF order [27] and by the consistency of our data with previously reported results (see discussion below). Also, recent neutron scattering experiments on CeCoIn₅, showing an anomalous increase in the vortex lattice form factor with increasing magnetic field [4], serve as additional evidence for the anomalous physics inside the vortex core.

We observe that the anomalous increase in flux flow resistivity is suppressed with increasing pressure (P) by plotting the normalized $\rho_{ff}/\rho_{ff}(H_{c2})$ vs. H/H_{c2} measured at $T/T_{c0} = 0.91$ (T_{c0} is the zero-field superconducting transition temperature) for different values of pressure [see Fig. 2(a)]. We attribute this suppression to the fact that the AF phase boundary moves deeper inside the SC dome with increasing pressure, diminishing the effect of critical fluctuations.

Our measurements also allow us to elucidate the phase boundary between the paramagnetic and antiferromagnetic phases inside the superconducting state. We noticed that a plot of the normalized flux-flow resistivity $\Delta\rho_{ff}(H)/\rho_{ff}(H_{c2})$ data vs $(\Delta H/H_{c2})^2(\Delta T/T_{c0})^2$ reveals a linear scaling behavior for same P and different H and T [see, for example, the $P = 0$ data of Fig. 2(b)]. Using this scaling of our experimental data, we were able to obtain the following equation for the antiferromagnetic boundary in the superconducting state (see supporting online material for more details):

$$\frac{P - P_c}{P^* - P_c} = \left(1 - \frac{T_N}{T_{c0}}\right) \left(1 - \frac{H_N}{H_{c2}(T_N)}\right), \quad (1)$$

where H_N is the corresponding value of the magnetic field at the AF transition. Here $P_c = -0.75$ GPa is the critical pressure (see online supplementary materials for details) and $P^* \approx 2.8$ GPa is taken as a pressure at which the tendency towards the antiferromagnetic order (or upturn in flux flow resistivity) is fully suppressed.

We note that a different value of $P^* \simeq 1.6$ GPa, defined as a crossover from a quantum-critical state for $P < P^*$ to a Fermi-liquid-like state for $P > P^*$, was previously obtained from resistivity measurements performed in the normal state [14]. The discrepancy between this value of P^* and the value determined in the present work could be due to the fact that, as in the case of high- T_c cuprate superconductors [28], the actual QCP of CeCoIn₅ deep inside the superconducting dome is shifted as a result of the competition between the antiferromagnetic and superconducting orders. Therefore, a direct measurement under the SC dome, as done in this work, is required to determine the actual H_{QCP} line.

The AF boundary (black line) in the T - P plane at $H = 0$ is shown in Fig. 3(a). We see that the AF and SC boundaries merge at P_c . For $P < P_c$, the SC phase is inside the AF dome, while for $P > P_c$, the AF phase coexists with superconductivity only inside the vortex cores. The up triangles and down triangles are $T_N(P)$ and $H_{c2}(P)$ data,

respectively, taken from Ref. [29], where 5% Cd doping corresponds to -0.7 GPa. In Ref. [29], the pressure P_c at which superconductivity and AF orders coincide is somewhere between -0.7 to -1 GPa, which agrees very well with $P_c = -0.75$ GPa determined from the present flux-flow resistivity data.

Equation (1) also allows us to *directly* determine the whole quantum critical phase boundary $H_{QCP}(P)$ from our ρ_{ff} measurements done in the mixed state. The antiferromagnetic boundary in the $H-P$ plane at $T = 0$, which represents the H_{QCP} line, is shown in Fig. 3(b) (red line). The upper critical field and quantum critical field boundaries merge at P_c . Data points denoted by daggers, open diamonds, and right- and left-hand triangles are data from Ref. [31].

We also plot on this figure QCP points previously reported in the literature, as extracted from different experimental techniques. The open circle is QCP determined at zero pressure through both Hall effect [16] and thermal expansion [17] measurements. This data point falls onto the presently determined $H_{QCP}(P)$ line. The solid diamonds are QCP points extracted by fitting resistivity data with $\rho = \rho_0 + a_0(H - H_{QCP})^{-n}$ in which an $n = 1.37$ was chosen in order to obtain $H_{QCP} = H_{c2}(0) = 5.1$ T at ambient pressure [15, 18]. Although these data points do not fall onto the present $H_{QCP}(P)$ line, we find that $n = 2$ can also be used to fit very well the same resistivity data, yielding $H_{QCP}(P = 0) = 4.1$ T, which is the same value as previously reported [16], and the newly obtained $H_{QCP}(P)$ points (solid circles) now follow very well the red $H_{QCP}(P)$ line, extracted from our present work. The yellow dotted line is the H_{QCP} line that we calculated using Eq. (2) of Ref. [30] with $H_{c2}(P = P_c) = 5.3$ T and our values of $P^* = 2.8$ GPa and $P_c = -0.75$ GPa. This theoretical curve overlaps remarkably well with our H_{QCP} line, with a small deviation at high pressure values, which is expected since the theoretical work only gives H_{QCP} close to P_c . Hence, this composite figure provides support for our analysis of the data and their interpretation. It also shows that the flux-flow measurement technique is a powerful tool to probe the subtle physics of the antiferromagnetic phase, which otherwise is undetectable because it is precluded by the superconducting transition.

We show in Fig. 3(c) the antiferromagnetic and superconducting boundaries in the $H-T$ plane at ambient pressure for CeCoIn₅. The open circles are upper critical field data taken from Ref. [17]. Equation (1), which gives the antiferromagnetic boundary, shows that this boundary is suppressed (T_N and H_N are suppressed) with increasing pressure, with the AF boundary being outside the SC dome for $P < P_c$, overlapping with the SC boundary at $P = P_c = -0.75$ GPa, entering the SC dome for $P > P_c$, and collapsing into the $H = T = 0$ point at $P = P^* \approx 2.8$ GPa. The inset shows the $H-T$ phase diagram of CeCo(In_{1-x}Cd_x)₅ ($x = 0.0075$) taken from Ref. [27] that corresponds to a chemical pressure of -1 GPa. This figure is consistent with the just discussed findings based on Eq. (1), showing that, indeed, for a negative pressure smaller than P_c , the AF boundary (red stars) is outside the superconducting dome.

To summarize, we observed a sharp increase in quasiparticle scattering inside the vortex core of CeCoIn₅ with decreasing H and T . We attribute this result to the presence of critical spin fluctuations near T_N inside the vortex core. This upturn in the vortex core resistivity is significantly suppressed by applied pressure, most likely since the AF order is suppressed with increasing P . Based on the scaling behavior of the vortex core resistivity, we identified the AF phase boundary within the SC dome as described by Eq. (1). In essence, these results provide evidence that the microscopic structure of the superconducting phase in CeCoIn₅ is highly unusual. The synergy of magnetism and superconductivity gives rise to a composite superconducting state in which conduction and magnetic degrees of freedom are strongly coupled to each other. Our experiment also shows the potential of the flux-flow measurement technique in probing the subtle features of unconventional superconductivity, in particular, how it competes with other phases, and in providing important insight into the nature of the interplay between quantum criticality, magnetism, and superconductivity in other strongly correlated systems such as iron-pnictides and copper oxides, as long as the pinning strength, and thermal and quantum fluctuations are small (see Supplementary material for details).
