(Dated: February 27, 2012)

We report on the spectroscopic quadrupole moment measurement of the 7/2− isomeric state in 43S, using the Time Dependent Perturbed Angular Distribution (TDPAD) technique at the RIKEN RIBF facility. Our value, |Qs| = 23(3) cm2, is larger than that expected for a single-particle state. Shell Model calculations using the modern SDPF-U interaction for this mass region reproduce remarkably well the measured |Qs|, and show that non negligible correlations drive the isomeric state away from a purely spherical shape.

Thanks to recent developments of intense radioactive beams, unexplored landscapes of the Ségré chart such as the structure of nuclei far from the stability line can now be investigated in detail. One of the most striking results from the last two decades is the modification or disappearance of the so-called “magic numbers” in exotic nuclei ascribed to proton-neutron interactions [15]. The latter would be responsible for the inversion between natural (i.e. rather spherical) and intruder (i.e. deformed) configurations in both 43S and 44S. For the 43S isomeric state [E∗ = 320.5(5) keV, T1/2 = 415(3) ns], the spin-parity Jπ = 7/2− resulting from the natural orbital configuration (νf7/2)−1 can be inferred from the very good agreement of SM calculations with the recently measured magnetic moment [γexp = −0.317(4), γSM = −0.280] [12]. The SM furthermore predicts that this normal configuration coexists with the intruder prolates deformed 3/2− ground state (g.s.).

In order to verify this scenario in 43S, two experimental observations are still missing: i) evidence for the rotational band built on top of the suspected intruder prolates ground state of the nucleus and ii) determination of the rather spherical nature of the isomeric state. In this letter we report on the measurement of the spectroscopic quadrupole moment of the 7/2− isomeric state using the TDPAD technique [16] on spin-aligned nuclei produced from an in-flight 48Si fragment beam [17–21]. The results suggest that correlations drive the isomeric state away from a purely spherical shape.

The TDPAD method was applied on spin aligned 43mSi
produced via the fragmentation of a 48Ca beam at both high intensity (4 μA) and energy (345.4 MeV). The primary beam impinging on a 4-mm thick 9Be target, located at the entrance of the BigRIPS spectrometer at the RIKEN RIBF facility in Japan [22]. The fully stripped fragments were selected through the spectrometer using a 15-mm thick Al achromatic degrader placed at the intermediate dispersive plane. Since the fragments time of flight was ≈ 430 ns in the nuclear frame, ≈ 50% of the produced 43S isomers reached the detection system located at the focal plane of the spectrometer at about 70 m from the production target. They were slowed down by a 10-mm thick Al degrader and implanted in an appropriate host material. A 0.1-mm thick plastic scintillator, located 1.5 m upstream from the host, provided a start signal for the TDPAD measurement and was used to monitor the implantation rate (≈ 8 × 10^7 out of 1.5 × 10^4 implanted fragments per second were 43S nuclei) and to determine the ion arrival time. The g factor of 43mS was first measured in order to validate the method and to perform the momentum selection where the spin-alignment was the highest. 43mS fragments were selected both in the center and the outermost wing of the longitudinal momentum distribution, and implanted in an annealed 3-mm thick Cu host placed between the poles of an electromagnet providing a static magnetic field B in the vertical direction with a strength B = 0.670(1) T. It was used to induce a Larmor precession of the spin-aligned 43mS fragments. The 320.5 keV γ-decay deexciting the isomer was recorded with four high-purity germanium detectors (HPGe), placed in the horizontal plane around the host at 45° with respect to the beam axis and 90° with respect to each other. Time and energy information were collected on an event-by-event basis. By gating on the 320.5 keV E2(7/2− → 3/2−) decay transition, the time spectrum of each detector were used to generate the ratio R(t):

$$R(t) = \frac{I_{34}(\theta = \pm 45^\circ, t) - \epsilon I_{12}(\theta = \pm 135^\circ, t)}{I_{34}(\theta = \pm 45^\circ, t) + \epsilon I_{12}(\theta = \pm 135^\circ, t)}$$

where $I_{ij}$ is the sum of the photo-peak intensities in Ge detectors $i$ and $j$, $\theta$ is the detection angle with respect to the beam axis, and $\epsilon$ is a normalization coefficient. The measured decay time of the 7/2− isomeric state yields a half-life of 415(3) ns. Figure 1 displays the R(t) functions for fragments selected a) in the center and b) in the wing of the momentum distribution. The amplitude of each oscillation is related to the amount of spin-alignment of the fragments [17]. In this case, the optimum alignment is achieved in the center of the momentum distribution with a value of +8.1(9)%. When selected in the outermost wing of the momentum distribution, the fragments exhibit an alignment of -2.8(6)%, limiting the accuracy in determining the g-factor. The g-factor extracted from the data set reported in Fig.1.a) amounts to −0.312(12), in agreement with that reported in Ref. [12]. Knowing $g$, one can determine the angle $\alpha$ [19] of the spin-orientation axis ($Z_{OR}$) (i.e. the symmetry axis of the spin-aligned ensemble) with respect to the beam axis at the implantation position. The angle is given by $\alpha = -\theta_c(1 - \frac{Q}{2Q})$, with $\theta_c = 60^\circ$ the angle between the 43S secondary beam at the target position and at the implantation position, $A$ and $Q$ the mass number and the charge state (here $Q = Z$) of the selected fragment. We find $\alpha = 86^\circ$.

For the quadrupole moment measurement, fragments were implanted in a pyrite (FeS2) single crystal host, providing an electric field gradient (EFG) $V_{zz}$. Fe atoms occupy a face-centered cubic sub-lattice in which sulfur atoms are grouped as $S_2$ dimers directed along ⟨111⟩ directions [23]. Consequently, the EFG has 4 components oriented along ⟨111⟩ axes at the sulfur positions. By orienting any of the three major axis ⟨100, 001⟩ or ⟨010⟩ along the beam one ⟨(010) in present case⟩, the four EFG components make an angle of ∼ 55° with respect to the beam and chosen axes. The highest anisotropy is found when gamma detectors are set perpendicular to the beam direction, as shown in Fig.2.
The photo-peak intensities used in Eq. (1) are \( I_i(t) = I_{0i} e^{-t/\tau} W(\theta_i, \phi_i, t) \), where \( \theta_i \) and \( \phi_i \) are the angles in spherical coordinates of detector \( i \) with respect to the laboratory reference frame, \( I_0 \) the photo-peak intensity at \( t = t_0 \) and \( \tau \) the lifetime of the isomeric state. The perturbed angular distribution \( W(\theta_i, \phi_i, t) \) is defined by perturbation coefficients, which consist of a superposition of harmonics with basic frequency \( \omega_0 = \frac{b_i^{232} e_0}{21} \), where \( \nu_Q \) is the quadrupole frequency \([24]\). The spectroscopic quadrupole moment \( Q_s \) can be deduced from the quadrupole frequency as \( Q_s = \nu_Q h/eV_{zz} \). The \( R(t) \) function is displayed in Fig. 3. A \( \chi^2 \)-minimization procedure was used to determine the parameters and their statistical errors. The free parameters in the fit were the amplitude, \( \nu_Q \) and \( t_0 \). Since the sign of \( Q_s \) is only accessible with a spin-polarized nuclear ensemble, only the absolute value was extracted. The value of the quadrupole frequency obtained is \(|\nu_Q|^{(43S, 7/2^-)}| = 76(3) \text{ MHz} \). The amount of alignment is \(+2.6(6)\%\), which corresponds to 32% of the alignment observed in the \( g \)-factor measurement for a similar selection of the momentum distribution. Possible reasons for such a reduction are that not all \( ^{43m}\text{S} \) fragments are implanted in a sulfur site in the \( \text{FeS}_2 \) host and there exist complex four EFG components in the crystal.

Using this value, the spectroscopic quadrupole moment of the \( 7/2^- \) isomer in \( ^{43}\text{S} \) is \(|Q_s(43\text{S}, 7/2^-)| = 23(3) \text{ efm}^2 \).

Shell model calculations were performed using the ANTOINE code \([34, 35]\) and the SDFP-U interaction \([37]\) within the full \( sd(fp) \) valence space for protons (neutrons) to compare with our result. Values for the effective charges \( e_\pi = 1.35e \), \( e_\nu = 0.35e \) and \( g \)-factors \( g_\pi^e = 1.1, g_\nu^e = 4.1895, g_\nu^e = -0.1, g_\nu^e = -2.8695 \) \([37]\) were used for protons and neutrons, respectively, in order to estimate electromagnetic properties. The present theoretical approach using the same interaction has already been shown to provide a fairly good description of the evolution of the nuclear structure from the stability line toward exotic neutron-rich nuclei at \( N = 27, 28 \) and \( 29 \) \([9–12, 14, 15, 36, 37]\). The calculated level scheme for \( ^{43}\text{S} \), restricted to states of interest here, is shown in Fig. 4. We note that the calculated excitation energy of the \( 7/2^- \) state \((E^* = 728 \text{ keV}) \) is overestimated by about 400 keV. This deviation could be ascribed to an underestimation of the binding energy of the isomeric state or an overestimation of the binding energy of the ground state. The calculated spectroscopic quadrupole moment of the \( 7/2^- \) isomer is \( Q_s^{SM} = +25 \text{ efm}^2 \), in remarkable agreement with the measured value. It is significantly larger than that expected for a single hole in the \( \nu f_{7/2} \) orbit, which is \( Q_{s,p} \approx 4 \text{ efm}^2 \). The latter was estimated from the simple relation \( Q_{s,p} = -e_\nu \frac{2j+1}{2j} \langle r_j^2 \rangle \), where \( e_\nu = 0.35e \) stands for the effective charge of the unpaired neutron lying in the \( f_{7/2} \) orbit, and \( \langle r_j^2 \rangle = 17 \text{ fm}^2 \) is the mean square radius for that orbit estimated using the wave function (WF) obtained from a Wood-Saxon potential with standard parameters. This single particle limit is in perfect agreement with that calculated within the present SM approach for \( ^{47}\text{Ca} \) \( [Q_s^{SM} (^{47}\text{Ca}_{g.s.}) = 3.9 \text{ efm}^2] \). The origin of the increased \( ^{43}\text{S} \) quadrupole moment is addressed in the following, using SM calculations.

Among the states calculated above the isomer, only the \( 9/2^- \) state shows strong electromagnetic transitions to the \( 7/2^- \) state (see Fig. 4). The reduced transition probabilities between higher angular momentum states and both the \( 7/2^- \) and \( 9/2^- \) states are weaker than those between the two latter states (see Fig. 4 for the \( 11/2^- \)). Therefore, present SM calculations do not show clear indication for deformed structure built on top of the \( 7/2^- \) isomer.

In order to get a better understanding of the structure of the isomer and higher lying states reported in Fig. 4, their WFs have been decomposed in terms of \textit{natural} and \textit{intruder} neutron configurations. The former corresponds to a single hole in the \( \nu f_{7/2} \) orbit, while the latter correspond to configurations for which at least one neutron has been promoted from the \( \nu f_{7/2} \) orbit toward higher \( fp \) orbits. The results of the decomposition are displayed in Fig. 5.

The ground state neutron WF of \( ^{43}\text{S} \) is dominated...
by intruder configurations, the natural one contributing less than 1%. We note that states belonging to the ground state rotational band predicted in that nucleus [12] exhibit similar WF decompositions. Experimentally the $7/2^{-}$ state has been identified as a rotational state [38, 39]. A more detailed description of the corresponding WFs in terms of proton and neutron components is shown in Fig. 7 of Ref. [36]. The natural neutron configuration $(\nu f_{7/2})^{-1}$ is the most prominent for the $7/2^{-}$ isomer (53%). However, intruder neutron configurations account for the rest of the neutron WF (i.e. 47%), most of which correspond to one and two neutron excitations across the N=28 shell gap (see Fig. 5). The natural neutron configuration is also found in higher lying states considered here, but its contribution gradually decreases while moving higher in excitation energy. Already for the $9/2^{-}$ state, the contribution of the $(\nu f_{7/2})^{-1}$ configuration is less than those from intruder configurations. The difference between the WF of the isomer state and the WFs of the states lying above the isomer corroborate the absence of deformed structure in these states. The non-negligible contribution of intruder configurations to the neutron WF of the isomer reflects the relatively large amount of multipole energy (i.e. correlation energy) contributing to the total energy of the isomer (see Ref. [14] for a detailed study in this mass region). Indeed, for the well correlated ground state of the nucleus, the correlation energy amounts to about 16 MeV, while for the $7/2^{-}$ isomer, it amounts to 13 MeV. These values should be compared to that found in Ca isotopes around $N=28$ of about 2 MeV. As recently shown, proton-neutron correlations give a large contribution to these values of correlation energy [15]. The latter induces non-negligible configuration mixing in the WF of the isomer responsible for the departure of its spectroscopic quadrupole moment from the single particle limit.

In summary, we report on the measurement of the quadrupole moment of the $7/2^{-}$ isomer in $^{43}$S using the TDPAD method on spin-aligned fragments selected through the BigRIPS separator at RIKEN. The measured spectroscopic quadrupole moment, $Q_{e}(^{43}S, 7/2^{-})=23(3)\text{ efm}^{2}$, is significantly larger than that expected for a single-particle state. Shell model calculations reproduce remarkably well our experimental value. Within this approach, no deformed structure is found on top of the isomer. Although the natural neutron configuration $(\nu f_{7/2})^{-1}$ is prominent in the the wave function of the isomer, SM calculations show that intruder neutron configurations arising from proton-neutron correlations have a non-negligible impact on the structure of this state. In particular, intruder configurations are understood to be reason behind the relatively large quadrupole moment reported for that state. 

Sensu stricto, the studied isomer in $^{43}$S cannot be regarded as a spherical state. However, while correlations are at play for this state, they are not developed enough to drive the state towards deformation since no deformed structure is predicted on top of it. Therefore the properties of the $7/2^{-}$ isomer in $^{43}$S are understood as a remnant effect of the eroding $N=28$ shell closure. In order to give unambiguous evidence of shape coexistence in the low-lying structure of $^{43}$S, it would be of great interest to experimentally identify the states belonging to the predicted rotational band built on top of the ground state.

The authors are thankful to the staff at RIBF at RIKEN and to T. Ahn for reading the manuscript. The experiment was performed under Program No. NP0906-RIBF06 at RIBF, operated by RIKEN Nishina Center and CNS, the University of Tokyo. This work was supported by the Japanese-French Hubert Curien partner-
ship (PHC), implemented by the Japanese Society for the Promotion Science (JSPS) and the French Ministère de l’Enseignement Supérieur et de la Recherche (MESR) et des Affaires Étrangères et Européennes (MAEE), the BriX IAP P6/23 project of OSTC Belgium, the Grant-in Aid for Scientific Research (No.20532089) of Japan, and the Bulgarian National Science Fund, grants DID-02/16 and DRNF-02/5.
