The mass and width of the lowest-lying S -wave spin singlet charmonium state, the η_c , are measured using a data sample of 1.06×10^8 $\psi(3686)$ decays collected with the BESIII detector at the BEPCII storage ring. We use a model that incorporates full interference between the signal reaction, $\psi(3686) \rightarrow \gamma\eta_c$, and a non-resonant radiative background to describe the line shape of the η_c successfully. We measure the η_c mass to be $2984.3 \pm 0.6 \pm 0.6$ MeV/ c^2 and the total width to be $32.0 \pm 1.2 \pm 1.0$ MeV, where the first errors are statistical and the second are systematic.

PACS numbers: 13.25.Gv, 13.20.Gd, 14.40.Pq

In recent years, many new charmonium or charmonium-like states have been discovered. These states have led to a revived interest in improving the quark-model picture of hadrons [1]. Even with these new discoveries, the mass and width of the lowest-lying charmonium state, the η_c , continue to have large uncertainties when compared to those of other charmonium states [2]. Early measurements of the properties of the η_c using J/ψ radiative transitions [3, 4] found a mass and width near 2978 MeV/ c^2 and 10 MeV, respectively. However, recent experiments, including photon-photon fusion and B decays, have reported a significantly higher mass and a much larger width [5–8]. The most recent study by the CLEO-c experiment [9], using both $\psi(3686) \rightarrow \gamma\eta_c$ and $J/\psi \rightarrow \gamma\eta_c$, pointed out a distortion of the η_c line shape in $\psi(3686)$ decays. CLEO-c attributed the η_c line-shape distortion to the energy dependence of the $M1$ transition matrix element.

In this Letter, we report measurements of the η_c mass

and width using the radiative transition $\psi(3686) \rightarrow \gamma\eta_c$. We successfully describe the measured η_c line shapes using a combination of the energy dependence of the hindered- $M1$ transition matrix element and a full interference with non-resonant $\psi(3686)$ radiative decays. The analysis is based on a $\psi(3686)$ data sample of 1.06×10^8 events [10] collected with the BESIII detector operating at the BEPCII e^+e^- collider. A 42 pb $^{-1}$ continuum data sample, taken at a center-of-mass energy of 3.65 GeV, is used to measure non- $\psi(3686)$ backgrounds.

The η_c mass and width are determined from fits to the invariant mass spectra of exclusive η_c decay modes. Six modes are used to reconstruct the η_c : $K_S K^+ \pi^-$, $K^+ K^- \pi^0$, $\eta \pi^+ \pi^-$, $K_S K^+ \pi^+ \pi^- \pi^-$, $K^+ K^- \pi^+ \pi^- \pi^0$, and $3(\pi^+ \pi^-)$, where the K_S is reconstructed in $\pi^+ \pi^-$, and the η and π^0 in $\gamma\gamma$ decays. The inclusion of charge conjugate modes is implied.

The BESIII detector is described in detail in Ref. [11]. The detector has a geometrical acceptance of 93% of

4 π . A small cell helium-based main drift chamber (MDC) provides momentum measurements of charged particles; in a 1 T magnetic field the resolution is 0.5% at 1 GeV/c. It also supplies an energy loss ($-dE/dx$) measurement with a resolution better than 6% for electrons from Bhabha scattering. The electromagnetic calorimeter (EMC) measures photon energies with a resolution of 2.5% (5%) at 1 GeV in the barrel (endcaps). The time-of-flight system (TOF) is composed of plastic scintillators with a time resolution of 80 ps (110 ps) in the barrel (endcap) and is mainly useful for particle identification. The muon system provides 2 cm position resolution and measures muon tracks with momenta greater than 0.5 GeV/c.

We use inclusive Monte Carlo (MC) simulated events as an aid in our background studies. The $\psi(3686)$ resonance is produced by the event generator KKMC [12], while the decays are generated by EvtGen [13] with known branching fractions [2], or by Lundcharm [14] for unmeasured decays. The signal is generated with an angular distribution of $1 + \cos^2 \theta_\gamma$ for $\psi(3686) \rightarrow \gamma \eta_c$, and phase space for multi-body η_c decays, where θ_γ is the angle between the photon and the positron beam direction in the center-of-mass system. Simulated events are processed using GEANT4 [15], where measured detector resolutions are incorporated.

We require that each charged track (except those from K_S decays) is consistent with originating from within 1 cm in the radial direction and 10 cm along the beam direction of the run-by-run-determined interaction point. The tracks must be within the MDC fiducial volume, $|\cos \theta| < 0.93$. Information from the TOF and $-dE/dx$ is combined to form a likelihood \mathcal{L}_π (or \mathcal{L}_K) for a pion (or kaon) hypothesis. To identify a track as a pion (kaon), the likelihood \mathcal{L}_π (\mathcal{L}_K) is required to be greater than 0.1% and greater than \mathcal{L}_K (\mathcal{L}_π).

Photons are reconstructed from isolated showers in the EMC that are at least 20 degrees away from charged tracks. The energy deposited in the nearby TOF scintillator is included to improve the reconstruction efficiency and the energy resolution. Photon energies are required to be greater than 25 MeV in the fiducial EMC barrel region ($|\cos \theta| < 0.8$) and 50 MeV in the endcap ($0.86 < |\cos \theta| < 0.92$). The showers close to the boundary are poorly reconstructed and excluded from the analysis. Moreover, the EMC timing, with respect to the collision, of the photon candidate must be in coincidence with collision events, *i.e.* $0 \leq t \leq 700$ ns, to suppress electronic noise and energy deposits unrelated to the event.

The $K_S \rightarrow \pi^+ \pi^-$ candidates are reconstructed from pairs of oppositely charged tracks. The secondary vertex constrained tracks must have an invariant mass ± 10 MeV/c² of the nominal K_S mass, and a decay length more than twice the vertex resolution. The track in-

formation at the secondary vertex is an input to the kinematic fit. Candidate π^0 and η mesons are reconstructed from pairs of photons with an invariant mass in the range $0.118 \text{ GeV}/c^2 < M(\gamma\gamma) < 0.150 \text{ GeV}/c^2$ for π^0 and $0.50 \text{ GeV}/c^2 < M(\gamma\gamma) < 0.58 \text{ GeV}/c^2$ for η . The remaining photons are considered as candidates of the transition photon.

Events with either extra charged tracks or non-zero net charge are rejected. The η_c candidates are reconstructed from $K_S K^+ \pi^-$, $K^+ K^- \pi^0$, $\eta \pi^+ \pi^-$, $K_S K^+ \pi^+ \pi^- \pi^-$, $K^+ K^- \pi^+ \pi^- \pi^0$ and $3(\pi^+ \pi^-)$. We select events in the region $2.7 \text{ GeV}/c^2 < M(\eta_c) < 3.2 \text{ GeV}/c^2$. A four-constraint (4C) kinematic fit of all selected charged particles and the transition photon with respect to the initial $\psi(3686)$ four-momentum is performed to reduce background and improve the mass resolution. When additional photons are found in an event, we loop over all possible combinations and keep the one with the best χ_{4C}^2 from the kinematic fit. The χ_{4C}^2 is required to be less than 60, a value is determined by optimizing the figure of merit for most of the channels, $S/\sqrt{S+B}$, where S (B) is the number of signal (background) events in the signal region ($2.9 \text{ GeV}/c^2 < M(\eta_c) < 3.05 \text{ GeV}/c^2$). In addition, to remove $\psi(3686) \rightarrow \pi^+ \pi^- J/\psi$ events, we require there be no $\pi^+ \pi^-$ pair with a recoil mass in the J/ψ signal region. To suppress background from $\pi^0 \rightarrow \gamma\gamma$, we demand that the transition photon should not form a π^0 with any other photon in the event.

The main source of background is from $\psi(3686) \rightarrow \pi^0 X_i$ decays, where a photon from the $\pi^0 \rightarrow \gamma\gamma$ decay is missing, and X_i represents the η_c final states under study. These decays could proceed via various intermediate states, and most of the branching fractions are unknown. To estimate their contribution, we reconstruct $\psi(3686) \rightarrow \pi^0 X_i$ decays from data. The selection criteria are similar to those applied to the $\gamma \eta_c$ candidates except an additional photon is required. The $\psi(3686) \rightarrow \pi^0 X_i$ signal yields are extracted from fits to the $M(\gamma\gamma)$ invariant mass distributions for different $M(X_i)$ mass bins. The relative efficiencies of the $\gamma \eta_c$ and $\pi^0 X_i$ selection criteria are estimated in each $M(X_i)$ mass bin using phase space distributed $\psi(3686) \rightarrow \pi^0 X_i$ MC events. Combining this relative efficiency with the number of $\psi(3686) \rightarrow \pi^0 X_i$ signal events in every $M(X_i)$ bin, we estimate the $\pi^0 X_i$ events that pass the $\gamma \eta_c$ selection. We also examine the efficiencies of $\pi^0 X_i$ events generated with different dynamics, and the change is negligible.

Other potential $\psi(3686)$ decay backgrounds are investigated using 1.06×10^8 inclusive MC events where $\pi^0 X_i$ events have been excluded. We find no other dominant background processes, but do find dozens of decay modes that each makes small additional contributions to the background. These decays typically have additional or fewer photons in their final states. The sum of these background events is used to estimate the

contribution from other $\psi(3686)$ decays. Backgrounds from the $e^+e^- \rightarrow q\bar{q}$ continuum process are studied using a data sample taken at $\sqrt{s} = 3.65$ GeV. Continuum backgrounds are found to be small and uniformly distributed in $M(X_i)$. There is also an irreducible non-resonant background, $\psi(3686) \rightarrow \gamma X_i$, that has the same final state as signal events. A non-resonant component is included in the fit to the η_c invariant mass.

Figure 1 shows the η_c invariant mass distributions for selected η_c candidates, together with the estimated $\pi^0 X_i$ backgrounds, the continuum backgrounds normalized by luminosity, and other $\psi(3686)$ decay backgrounds estimated from the inclusive MC sample. A clear η_c signal is evident in every decay mode. We note that all of the η_c signals have an obviously asymmetric shape: there is a long tail on the low-mass side; while on the high-mass side, the signal drops rapidly and the data dips below the expected level of the smooth background. This behavior of the signal suggests possible interference with the non-resonant γX_i amplitude. In this analysis, we assume 100% of the non-resonant amplitude interferes with the η_c .

The solid curves in Fig. 1 show the results of an unbinned simultaneous maximum likelihood fit in the range from 2.7 to 3.2 GeV/ c^2 with three components: signal, non-resonant background, and a combined background consisting of $\pi^0 X_i$ decays, continuum, and other $\psi(3686)$ decays. The signal is described by a Breit-Wigner (BW) convolved with a resolution function. The non-resonant amplitude is real, and is described by an expansion to second order in Chebychev polynomials defined and normalized over the fitting range. The combined background is fixed at its expected intensity, as described earlier. The fitting probability density function (PDF) as a function of mass (m) reads:

$$F(m) = \sigma \otimes \left[\epsilon(m) \left| e^{i\phi} E_\gamma^{7/2} \mathcal{S}(m) + \alpha \mathcal{N}(m) \right|^2 \right] + \mathcal{B}(m)$$

where $\mathcal{S}(m)$, $\mathcal{N}(m)$ and $\mathcal{B}(m)$ are the signal, the non-resonant γX_i component, and the combined background, respectively; E_γ is photon energy; σ is the experimental resolution and $\epsilon(m)$ is the mass-dependent efficiency. The E_γ^7 multiplying $|s(m)|^2$ reflects the expected energy dependence of the hindered-M1 transition [16], which partially contributes to the η_c low mass tail as well as the interference effect. The interference phase, ϕ , and the strength of the non-resonant component, α , are allowed to vary in the fit.

The mass-dependent efficiencies are determined from phase space distributed MC simulations of the η_c decays. Efficiencies obtained from MC samples that include intermediate states change the resulting mass and width by negligible amounts. MC studies indicate that the resolution is almost constant over the fitting range. Thus, a mass-independent resolution is used in the fit. The

detector resolution is primarily determined by MC simulation for each η_c decay mode. The consistency between the data and MC simulation is checked by the decay $\psi(3686) \rightarrow \gamma\gamma J/\psi$, where the J/ψ decays into the same final states as the η_c . We use a smearing Gaussian function to describe possible discrepancies between data and MC. By fitting the MC-determined J/ψ shape convolved by a smearing Gaussian function to the data, we determine the parameters of the Gaussian function. Due to the different kinematics, the parameters are slightly different for each mode.

In the simultaneous fit, the η_c mass and width are constrained to be the same for all the decay modes but still free parameters; the two Chebychev polynomial coefficients and the factor α are also allowed to float. Two solutions for the relative phase are found for each decay mode, one corresponds to constructive and the other destructive interference between the two amplitudes at the η_c peak. Regardless of which solution we take, the mass, width of the η_c and the overall fit quality are always unchanged [17]. The mass is $M = 2984.3 \pm 0.6$ MeV/ c^2 , and width $\Gamma = 32.0 \pm 1.2$ MeV. The goodness-of-fit $\chi^2/ndf = 283.4/274$, which indicates a reasonable fit. The solutions for relative phase of each mode are listed in Table I.

TABLE I: Solutions of relative phase (in unit of radian) of each decay mode.

mode	constructive	destructive
$K_S K^+ \pi^-$	2.94 ± 0.27	3.75 ± 0.26
$K^+ K^- \pi^0$	2.63 ± 0.21	3.96 ± 0.19
$\eta \pi^+ \pi^-$	2.41 ± 0.13	4.28 ± 0.09
$K_S K^+ \pi^+ \pi^- \pi^-$	2.16 ± 0.11	4.46 ± 0.07
$K^+ K^- \pi^+ \pi^- \pi^0$	2.73 ± 0.19	4.00 ± 0.16
$3(\pi^+ \pi^-)$	2.28 ± 0.10	4.43 ± 0.06

However, without the interference term, the fit would miss some data points especially where the symmetric shape of BW is deformed, and the goodness-of-fit is $\chi^2/ndf = 426.6/280$. The statistical significance of the interference, calculated based on the differences of likelihood and degrees of freedom between fits with and without interference, is of order 15σ .

The systematic uncertainties of the η_c mass and width mainly come from the background estimation, the mass scale and resolution, the shape of the non-resonant component, the fitting range, and the efficiency.

In the fit, the $\pi^0 X_i$ background is fixed at its expected intensity, so the statistical uncertainty of the observed $\pi^0 X_i$ events introduces a systematic error. To estimate this uncertainty, we vary the number of events in each bin by assuming Gaussian variations from the expected value. We repeat this procedure a thousand times, and

FIG. 1: The $M(X_i)$ invariant mass distributions for the decays $K_S K^+ \pi^-$, $K^+ K^- \pi^0$, $\eta \pi^+ \pi^-$, $K_S K^+ \pi^+ \pi^-$, $K^+ K^- \pi^+ \pi^-$ and $3(\pi^+ \pi^-)$, respectively, with the fit results (for the constructive solution) superimposed. Points are data and the various curves are the total fit results. Signals are shown as short-dashed lines, the non-resonant components as long-dashed lines, and the interference between them as dotted lines. Shaded histograms are (in red/yellow/green) for (continuum/ $\pi^0 X_i$ /other $\psi(3686)$ decays) backgrounds. The continuum backgrounds for $K_S K^+ \pi^-$ and $\eta \pi^+ \pi^-$ decays are negligible.

take the standard deviation of the resulting mass, width, and phases as systematic errors. We also use different dynamics in generating the $\pi^0 X_i$ events (with the same final state, but different intermediate states) for the efficiency correction, and find the differences in resulting mass and width are small. We take $0.24 \text{ MeV}/c^2$ in mass and 0.44 MeV in width as the systematic errors for the $\pi^0 X_i$ background estimation.

We assign a $0.07 \text{ MeV}/c^2$ (0.06 MeV) error in mass (width) for the non-resonant component shape that is obtained by changing the polynomial order. Also we include an additional non-interfering component, which is represented by a 2nd-order polynomial with free strength and shape parameters. The changes in the resulting η_c mass and width are $0.10 \text{ MeV}/c^2$ and 0.02 MeV , respectively; and the fraction of this component to total non-resonant rate varies from 0 to 25% depending on decay mode. These variations are included in systematic errors.

The systematic error from the uncertainty in the other $\psi(3686)$ decay backgrounds is estimated by floating the magnitude and changing the shape of this component to a 2nd-order polynomial with free parameters. The changes, $0.05 \text{ MeV}/c^2$ in mass and 0.06 MeV in width, are taken as systematic errors.

The consistency of the mass scale and resolution between data and MC is checked with the decay $\psi(3686) \rightarrow \gamma \gamma J/\psi$, and possible discrepancies are described by a smearing Gaussian distribution, where a non-zero mean

value indicates a mass offset, and a non-zero σ represents difference between the data and MC mass resolutions $(\sigma_{\text{data}}^2 - \sigma_{\text{MC}}^2)^{1/2}$. A typical mass shift is about $-1.0 \text{ MeV}/c^2$ and resolution smear is $\sim 3.0 \text{ MeV}$. Another possible bias is the difference between input and the value after event-reconstruction and selection. This is small for both the mass shift ($< 0.3 \text{ MeV}$) and resolution smear. Both of these are added in the smearing Gaussian distribution. By varying the parameters of the smearing Gaussian distribution from the expected value, we estimate the uncertainties. From a large number of tests, the standard deviation of the resulting mass (width), $0.38 \text{ MeV}/c^2$ (0.27 MeV), is taken as a systematic error in mass (width) for the mass scale uncertainty. A $0.35 \text{ MeV}/c^2$ (0.60 MeV) systematic error in mass (width) is assigned due to the mass resolution uncertainty.

The systematic error due to the fitting range is estimated by varying the lower-end between 2.6 and $2.8 \text{ GeV}/c^2$ and the higher-end between 3.1 and $3.3 \text{ GeV}/c^2$. The changes, $0.05 \text{ MeV}/c^2$ in mass and 0.07 MeV in width, are assigned as systematic errors. A mass-dependent efficiency is used in the fit. By removing the efficiency correction from the fitting PDF, the changes, which are $0.05 \text{ MeV}/c^2$ in mass and 0.06 MeV in width, are taken as systematic errors. The stability of the simultaneous fit program is checked by repeating the fit a thousand times with random initialization; the

standard deviation of mass and width, $0.14 \text{ MeV}/c^2$ and 0.66 MeV , respectively, are taken as systematic errors.

We assume all these sources are independent and take their sum in quadrature as the total systematic error. We obtain the η_c mass and width to be

$$\text{mass} = 2984.3 \pm 0.6 \pm 0.6 \text{ MeV}/c^2,$$

$$\Gamma = 32.0 \pm 1.2 \pm 1.0 \text{ MeV}.$$

Here (and elsewhere) the first errors are statistical and the second are systematic.

The relative phases for constructive interference or destructive interference from each mode are consistent with each other within 3σ , which may suggest a common phase in all the modes under study. A fit with a common phase (*i.e.* the phases are constrained to be the same) describes the data well, with a $\chi^2/ndf = 303.2/279$. Comparing to the fit with separately varying phases for each mode, we find the statistical significance for the case of five distinct phases to be 3.1σ . This fit yields $M = 2983.9 \pm 0.6 \pm 0.6 \text{ MeV}/c^2$, $\Gamma = 31.3 \pm 1.2 \pm 0.9 \text{ MeV}$, and $\phi = 2.40 \pm 0.07 \pm 0.47 \text{ rad}$ (constructive) or $\phi = 4.19 \pm 0.03 \pm 0.47 \text{ rad}$ (destructive). The physics behind this possible common phase is yet to be understood.

In summary, we measure the η_c mass and width via $\psi(3686) \rightarrow \gamma\eta_c$ by assuming all radiative non-resonant events interfere with the η_c . These results are so far the most precise single measurement of the mass and width of η_c [2]. For the first time, interference between the η_c and the non-resonant amplitudes around the η_c mass is considered; given the assumptions of our fit, the significance of the interference is of order 15σ . We note that this interference affects the η_c mass and width significantly, and may have impacted all of the previous measurements of the η_c mass and width that used radiative transitions. Our results are consistent with those from photon-photon fusion and B decays [5–8]; this may partly clarify the discrepancy puzzle discussed above. The changes of the η_c mass and width may also have an impact on the expected η'_c mass and width, and will modify the parameters used in charmonium potential models, where the η_c mass is one of the input parameters. From this measurement, we determine the hyperfine mass splitting to be $\Delta M_{hf}(1S)_{c\bar{c}} \equiv M(J/\psi) - M(\eta_c) = 112.6 \pm 0.8 \text{ MeV}/c^2$, which agrees well with recent lattice computations [18–20] as well as quark model predictions [21], and sheds light on spin-dependent interactions in quarkonium states.

The BESIII collaboration thanks the staff of BEPCII and the IHEP computing center for their strong efforts.
