(Dated: July 18, 2012)

We use numerical linked cluster (NLC) expansions to compute the specific heat, $C(T)$, and entropy, $S(T)$, of a quantum spin ice Hamiltonian for Yb$_2$Ti$_2$O$_7$ using anisotropic exchange interactions recently determined from inelastic neutron scattering measurements and find good agreement with experimental calorimetric data. This vindicates Yb$_2$Ti$_2$O$_7$ as a model quantum spin ice. We find that in the perturbative weak quantum regime, such a system has a ferrimagnetic ordered ground state, with two peaks in $C(T)$: a Schottky anomaly signalling the paramagnetic to spin ice crossover followed at lower temperature by a sharp peak accompanying a first order phase transition to the ordered state. We suggest that the two $C(T)$ features observed in Yb$_2$Ti$_2$O$_7$ are associated with the same physics. Spin excitations in this regime consist of weakly confined spinon-antispinon pairs. We anticipate that conventional ground state with exotic quantum dynamics will prove a prevalent characteristic of many real quantum spin ice materials.

The experimental search for quantum spin liquids (QSLs), magnetic systems disordered by large quantum fluctuations, has remained unfaired for over twenty years [1]. One direction that is rapidly gathering momentum is the search for QSLs among materials that are close relatives to spin ice systems [2], but with additional quantum fluctuations, or quantum spin ice (QSI) [3, 4].

Spin ice materials, such as R$_2$M$_2$O$_7$ (R=Ho, Dy; M=Ti, Sn), have magnetic rare-earth atoms (Ho, Dy) at the vertices of a pyrochlore lattice of corner-sharing tetrahedra [2, 5]. The combination of large single ion anisotropy and exchange and dipolar interactions lead to an exponentially large number of low-energy states characteristic of many real quantum spin ice materials.

Spin ice states, with two peaks in $C(T)$ features observed in Yb$_2$Ti$_2$O$_7$ are associated with the same physics. Spin excitations in this regime consist of weakly confined spinon-antispinon pairs. We anticipate that conventional ground state with exotic quantum dynamics will prove a prevalent characteristic of many real quantum spin ice materials.

FIG. 1: (a) Two neighboring tetrahedra with spins in their two-in/two-out ground state, (b) spinon/antispinon pair, (c) spinon/antispinon pair separated by a (green) string of misaligned spins in the pyrochlore lattice.
are not amenable to large-scale quantum Monte Carlo simulations because of the so-called sign problem. While the density matrix renormalization-group (DMRG) is a powerful method for 1-dimensional systems, and exact diagonalization has proved useful in two-dimensions, these methods are much less useful in three-dimensions. Using YbTO as a benchmark, we show below that NLC allows for a reliable and accurate calculation of thermodynamic properties of such systems as a function of temperature in the regime of short-range correlations and over a range of parameters.

Anisotropic exchange interactions, \( \{ J_e \} \), are expected to drive exotic quantum physics, including QSI, in pyrochlore oxides [3, 4, 16, 23, 28]. While these have been argued to be at play in YbTO for some time [14], there is at present no consensus as per their values [14–16, 19–21], an issue that stands in the way of making progress in understanding this system. By calculating the specific heat, \( C(T) \), in a reliable manner using NLC expansions, we show that the \( \{ J_e \} \) values of Ross et al. [16] provide excellent agreement with experiments, hence validating their exchange parameters over others [14, 15, 19, 20, 21].

We also find an excellent agreement between the theoretical entropy, \( S(T) \), calculated for YbTO parameters, by going down in \( T \) starting from a value of \( k_B \ln 2 \) at \( T = \infty \), and the experimental entropy obtained by assuming zero entropy at \( T = 0 \) and integrating the \( C(T)/T \) data through the sharp peak around 0.24 K. This agreement does suggest that the experimentally observed sharp peak in YbTO may be consistent with the model. However, since our numerical results are valid only at relatively high \( T \), we can not rule out the possibility that the model may have an entropy that would only decrease gradually to zero as \( T \) goes to zero without displaying a transition. Such a second peak, and the development of long-range order, is also found in our Monte Carlo simulations of a pertinent effective classical model.

Finally, we use perturbative arguments to show that despite a conventional ground state, the spin excitations consist of spinon/antispinon pairs connected by (Dirac-like [31, 32]) strings of reversed spins, whose confinement length \( l_s \) diverges in the limit of small quantum exchanges. We propose that these excitations should ultimately form the basis for describing what we expect to be highly unconventional inelastic neutron spectra [24].

**Model & Method** – The anisotropic exchange QSI model is defined by the nearest-neighbor Hamiltonian [16, 23] on the pyrochlore lattice

\[
\hat{H}_{\text{QSI}} = \sum_{<i,j>} \left\{ J_{zz} S_i^z S_j^z - \lambda J_{\pm} (S_i^x S_j^x + S_i^y S_j^y) + \lambda J_{\pm} \left[ \gamma_{ij} S_i^z S_j^+ + \gamma_{ij}^* S_i^- S_j^z \right] + \lambda J_{\pm} \left[ \zeta_{ij} S_i^x S_j^y + \zeta_{ij}^* S_i^y S_j^x \right] + i \leftrightarrow j \right\} \tag{1}
\]

\( \gamma_{ij} \) is a \( 4 \times 4 \) complex unimodular matrix, and \( \zeta = -\gamma^* \) [16]. The \( z \) quantization axis is along the local \([111] \) direction, and \( \pm \) refers to the two orthogonal local directions. We take \( \lambda = 1 \), except when stated otherwise.

Recently Ross et al. [16] used inelastic neutron scattering data in high magnetic field to deduce the \( \{ J_e \} \) exchange parameters for YbTO: \( J_{zz} = 0.166 \pm 0.04 \), \( J_+ = 0.05 \pm 0.01 \), \( J_- = 0.05 \pm 0.01 \), and \( J_{\pm} = -0.14 \pm 0.01 \), all in meV. These parameters have also been determined through an analysis of the zero-field energy-integrated paramagnetic neutron scattering [15, 19], but the values of the \( \{ J_e \} \) parameters disagree significantly – an issue that we address in the Supplementary Material [33].

We calculate the thermodynamic properties of the model (1) using an NLC expansion that includes all contributions from clusters up to four tetrahedra [29, 30, 33]. Such an expansion is numerically exact in two limits. It is so at high temperature because the contributions from larger clusters neglected here are \( O(\beta^6) \), where \( \beta \equiv 1/T \). It is also exact at high-field \( h \) at all temperatures, because corrections are \( O((J/h)^3) \) at \( T = 0 \), with further exponentially small corrections \( \exp (-c h/T) \) at \( T \neq 0 \). The only region where it is not necessarily accurate is when both \( T \) and \( h \) are small. A tetrahedron-based NLC is particularly suited to spin ice related systems. Indeed, it was recently shown that for classical spin ice models, just first order NLC is equivalent to the Pauling approximation [6] and gives \( C(T) \) and \( S(T) \) for all \( T \) within a few percent accuracy [34]. Euler extrapolations [35] are used to further improve the convergence of the calculations at low \( T \). Details on the NLC expansions can be found in the Supplementary Material [33].

Figure 2 shows \( C(T) \) calculated with different NLC orders. By 4th order, there is good convergence to temperatures below the \( C(T) \) peak at \( \sim 2 \) K. Applying Euler transformations [35] improves the convergence down to slightly below 1 K. The experimental data from Refs. [25], shown for comparison, agree well with the NLC results. This agreement shows that the \( \{ J_e \} \) parameters are not substantially changed compared to the high-field \( (h = 5 \text{ Tesla}) \) values [16]. Using the \( \{ J_e \} \) of Refs. [15, 19] gives substantially different \( C(T) \) results [33].

Figure 3 shows \( S(T) \) calculated by NLC, together with the entropy obtained by integrating the experimental \( C(T)/T \) data of Ref. [25], which we found ideally suited to perform a comparison with NLC [33]. The entropy converges to lower temperature slightly better than \( C(T) \) where, with Euler transformations, \( S(T) \) converges down to about 0.7 K, matching well with the experimental entropy values over the overlapping temperature range. Note that the agreement of the NLC \( S(T) \) with the experimental \( S(T) \) is not redundant with the agreement found above for \( C(T) \) (since \( S(T_2) - S(T_1) = \int_{T_1}^{T_2} \left( \frac{C(T)}{T} \right) dt \)). The experimental \( S(T) \) was obtained assuming a zero residual entropy at \( T_1 \lesssim 100 \text{ mK} \) \( (S^{\text{exp}}(T_1) = 0) \) while the NLC \( S(T) \) was obtained taking the paramagnetic entropy \( S^{\text{NLC}}(T_2 \rightarrow \infty) \) to be \( k_B \ln(2) \). Hence, there is no a pri-
because, once a spin is flipped in a spin-ice state, creating
tions remain non-trivial and of quantum nature. This is
strings – A surprise of the perturbative treatment is that,
to the aforementioned
$C$ model [33]. These reveal a very sharp lower temperature
$s$ical loop Monte Carlo simulations [37] of the

or reason why the two entropies should mesh so well
with each other in the 0.7 K – 4 K temperature range
where strong correlations develop [15, 16]. Thus, the
observed $S(T)$ agreement between experiment and NLC,
along with that for $C(T)$ in Fig. 2, provides compelling
evidence that we have at hand with Eq. (1) a quantita-
tive model of Yb$_2$Ti$_2$O$_7$, which may also explain the phase
transition around 0.24 K. This is the main result of this
paper.

Perturbative considerations – We now turn to the
perturbative regime $\lambda \ll 1$ in Eq. 1 [16, 23]. To second
order in $\lambda$, only $J_{z\pm}$, by far the largest quantum term
for Yb$_2$Ti$_2$O$_7$, leads to a degeneracy-lifting classical poten-
tial for different spin-ice configurations. It amounts to
$\lambda$ order in $\lambda$ and $\lambda J_{z\pm}$, only
$J_{z\pm}$ in Eq. 1 [16, 23]. To second
order processes involving closed loops with alter-

Excited states in the perturbative regime: spinons and
strings – A surprise of the perturbative treatment is that,
while the ground state is classical, the spin-flip excita-
tions remain non-trivial and of quantum nature. This is
because, once a spin is flipped in a spin-ice state, creating
a spinon/antispinon pair [32], the pair can hop through
$J_{z\pm}$ acting through first order degenerate perturbation
theory. Thus, the dispersion bandwidth in the excited
state manifold is $O(\lambda J_{z\pm})$, much larger than the disper-
sion within the low-energy manifold of spin ice states,
which is only $O(\lambda^2 J_{z\pm}^2 / J_{zz})$.

A sketch of a spinon/antispinon pair is shown in Figs.
1b and 1c. Note that only spins inside the tetrahe-
dron “already” containing spinons are flippable in first
order degenerate perturbation theory. Hence, the con-
necting string of misaligned spins can only fluctuate by
higher order processes involving closed loops with alter-
ating in-out spins [24]. Thus the renormalized string
tension per unit length remains finite and of order $J_3$.
One can estimate the typical string length as the length,$l_s$, at which the cost of the string becomes compar-
able to the delocalization energy of the spinon/antispinon
pair. The string energy per unit length goes as $\sim J_3 \sim
\lambda^2 J_{z\pm}^2 / J_{zz}$, whereas the delocalization energy (spinon
bandwidth) goes as $\lambda J_{z\pm} / J_{zz}$. This gives $l_s$ scaling as
$(1/\lambda)(J_{zz} / J_{z\pm})$, which diverges as $\lambda J_{z\pm} \rightarrow 0$. The
spinon/antispinon, with accompanying strings, are a de-
scription of the excitations most useful in the limit of
small $\lambda$. As one moves farther from the $J_3 = J_{z\pm} = 0$ clas-
sical spin ice and into the ferrimagnetic regime, a
conventional magnon description may become more ade-
quate. In the intermediate regime, either description
would require consideration of strong scattering of their

FIG. 2: Heat capacity, $C(T)$, per mole of Yb for the model
parameters in Ref. [16], in units of the Boltzmann constant
kB, calculated via NLC (up to 4th order NLC together with Euler
extrapolations) are compared with experimental data
for Yb$_2$Ti$_2$O$_7$. The black circles are data from Ref. [25].

FIG. 3: Entropy, $S(T)$, per mole of Yb, in units $k_B$ following
the methods described in the caption of Fig. 2. The black
circles are obtained by integrating the data from Ref. [25]
excluding the nuclear (hyperfine) contribution. The Pauling
entropy $S_P \sim \frac{1}{k_B} \ln \frac{1}{2}$ is shown as a horizontal line. The inset
shows $S(T)$ in the perturbative regime with $J_3 / J_{zz} = -0.001$.
A clear plateau at $S(T) \approx S_P$ is seen, followed at lower $T$ by
a precipitous drop of $S(T)$ (i.e. latent heat) accompanying
the transition to long range FM order [33].
Comparing lower than mean-field theory by an order of magnitude. It shows that in the classical $J_{16}$, the low temperature of YbTO so low? As discussed by Ross above the transition to the magnetic phase is not attempted here, but we anticipate quasi-particles (spinons or magnons).

A detailed theory of neutron scattering in this ferrimagnetic phase is not attempted here, but we anticipate it to follow the proposal of Ref. [24]. At temperatures above the transition to the $\mathbf{q} = 0$ long-range ordered state, the system explores the classical two-in/two-out spin ice states and should display singularities (pinch points, PPs) in neutron scattering [38] rounded off by the finite density of thermally excited spinon/antispinon defects [32, 38]. While the system has thermally smeared PPs above the ferrimagnetic transition and no static PPs well below the transition, it may display some remnant of PPs in the spin dynamics at higher energies [39]. These interesting issues deserve further attention. We note in passing that very recent work explores the neutron scattering properties of a minimal QSI model [39].

Beyond the $\lambda \ll 1$ regime – Why is the transition temperature of YbTO so low? As discussed by Ross et al. [16], the low $T$ peak in $C(T)$ is at a temperature lower than mean-field theory by an order of magnitude. Comparing $C(T)$ for the quantum model with different $\lambda$ with the corresponding classical model with the perturbative $J_3/J_{zz}$ value provides a hint of the reason why [33]. It shows that in the classical $J_{zz} - J_3$ model the long-range order moves steadily up with increasing $J_3$, even beyond the short-range order $C(T)$ peak. In contrast, the quantum systems with different $\lambda$ continue to display a short-range order $C(T)$ peak and presumably long-range order only occurs at a much lower $T$.

Another reason for a reduced $T_c$ comes from considering the temperature dependence of the defect (spinon/antispinon) density [32], $\rho(T)$, as calculated by NLC (see Fig. 4 and Figs. S3 and S4 [33]). To illustrate the point, we show $\rho(T)$ for several different $\lambda$ values. Convergence increases to lower $T$, with decreasing $\lambda$, as expected. One finds that as $T$ drops below the hump in $C(T)$, $\rho(T)$ displays a plateau-like region, whose value increases steadily with increasing $\lambda$. This indicates that the states within the spin-ice manifold develop large spinon/antispinon spectral weight, thus strongly renormalizing all low energy scales and, presumably, leading to a reduced $T_c$.

Discussion: What constitutes an exchange QSI? – We suggest that a double-peaked $C(T)$ with an entropy between the peaks comparable to $S_P$ is the hallmark of an exchange quantum spin ice (QSI). However, one is unlikely to find an exact plateau at $S(T) \approx S_P$ outside the perturbative (small $\lambda$) regime (see Fig. 3) [33]. Evidence for such a double-peaked structure and quasi-separation of the energy/temperature regime (see Fig. 3) [33].

According to the gauge mean-field theory of Ref. [23], at low temperature below which short-range spin ice correlations develop, a system may exhibit either conventional ferrimagnetic (FM) order, a Coulombic ferromagnet (CFM) or a full-blown quantum spin-liquid (QSL), depending on its exchange parameters. The largest quantum exchange term in YbTO is $J_{zz}$ which favors the FM state and which we believe is the origin of the 0.24 K transition in the best samples [17, 18, 26]. It remains to be seen if there exist materials for which $J_{zz}$, that favors the QSL [9, 10, 23], is the dominant quantum term. Since $J_{zz}$ is zero for non-Kramers ions (e.g. Pr, Tb) [28], and virtual crystal field excitations [3] in Tb-based pyrochlores are a fundamentally different pathway from anisotropic superexchange [4] to generate anisotropic $\{J_e\}$ couplings between effective spins $1/2$ [3, 4], the prospect to eventually find a QSI-based QSL among rare-earth pyrochlores [5] is perhaps promising.

Having demonstrated through NLC expansions that the anisotropic exchange model of Eq. (1) with the $\{J_e\}$ values of Ref. [16] describes quantitatively Yb$_2$Ti$_2$O$_7$, we anticipate that NLC will also be useful to successfully describe other magnetic pyrochlore oxides and other highly-frustrated three-dimensional magnetic systems for which there are essentially no other reliable unbiased quantitative methods available.

This work is supported in part by NSF grant number DMR-1004231, the NSERC of Canada and the Canada Research Chair program (M.G., Tier 1). We acknowledge very useful discussions with P. Holdsworth, B. Janvanparast, K. Ross and J. Thompson. We thank P. Dalmas de Réotier for providing the specific heat data of Ref. [17].

---
