DOI: [10.1103/PhysRevLett.109.137004](https://doi.org/10.1103/PhysRevLett.109.137004)
Low-temperature scanning tunneling microscopy and spectroscopy are employed to investigate twin boundaries in stoichiometric FeSe films grown by molecular beam epitaxy. Twin boundaries can be unambiguously identified by imaging the 90° change in the orientation of local electronic dimers from Fe site impurities on either side. Twin boundaries run at approximately 45° to the Fe-Fe bond directions, and noticeably suppress the superconducting gap, in contrast to the recent experimental and theoretical findings in other iron pnictides. Furthermore, vortices appear to accumulate on twin boundaries, consistent with the degraded superconductivity there. The variation in superconductivity is likely caused by the increased Se height in the vicinity of twin boundaries, providing the first local evidence for the importance of this height to the mechanism of superconductivity.

The response of superconductivity to crystal defects is crucial to two forefront technological issues, namely the sharpness of the superconducting transition and the critical current. Many early studies have revealed a slight enhancement in the superconducting critical temperature $T_c$ near twin boundaries (TBs) of certain conventional superconductors such as In, Sn and Nb [1]. Meanwhile, TBs tend to pin vortices and so enhance the critical currents in the cuprate high-$T_c$ superconductor YBa$_2$Cu$_3$O$_{7-δ}$ (YBCO) [2, 3]. The general interplay of TBs and superconducting properties remains unresolved.

In the recently discovered iron-based compounds, the tetragonal-to-orthorhombic distortion above $T_c$ typically generates a maze of TBs upon cooling [4], which serves as a test bed for twinning-plane superconductivity. Local susceptometry measurements with a scanned superconducting quantum interference device (SQUID) show an enhanced superfluid density along TBs in underdoped Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ [5, 6], compatible with SQUID magnetometry images where vortices avoid pinning on TBs [7]. On the other hand, doping-dependent TB imaging with polarized light, combined with bulk critical current determination in Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$, shows a tremendous enhancement of critical current at the doping level where TBs are densest, leading to a claim that vortices are pinned on TBs [8]. However, in the absence of direct vortex imaging, this latter observation is also consistent with the possibility that the critical current is enhanced by vortex trapping between the TBs. Bitter decoration in Ba(Fe$_{1-x}$Ni$_x$)$_2$As$_2$ shows vortices clustered along lines in some regions of the sample, leading to a claim of TB pinning [9]. But the absence of simultaneous twin boundary imaging again leaves open the possibility that the aligned vortices are pinned on domains between parallel TBs.

These experiments on iron-based superconductors have used magnetic imaging techniques, whose resolution is limited to approximately the penetration depth $\lambda \sim 325$ nm [10]. Because pinning may occur on the vortex core length scale, $\xi \sim 3$ nm [11], it can be challenging in some cases to determine from magnetic imaging alone whether a vortex is pinned on or near the TB. Scanning tunneling microscopy/spectroscopy (STM/STS), which can image both TBs and vortices on the $\xi$ length scale, can address this issue with a better resolution [12]. Additionally, in most cuprates and iron pnictides, chemical doping plays an essential role in superconductivity; thus its possible variation across TBs may complicate the understanding of the twinning-plane superconductivity [13]. As an alternative, the stoichiometric and structurally simple PbO-type $\beta$-FeSe superconductor provides a unique system for addressing the variations in superconductivity near TBs [14].

Here we report on STM/STS studies of TBs in stoichiometric and superconducting FeSe films grown by molecular beam epitaxy (MBE). This allows for a direct probe of the superconducting order parameter near TBs at the nanometer length scale. Sparse Se atoms at near-surface Fe sites produce local dimer-like scattering signatures. TBs are identified by the 90° rotations of the electronic dimers on either side, and are seen to roughly orient along the diagonals of the Fe unit cells. We observe that (1) TBs considerably suppress the superconducting gap within the coherence length, and (2) vortices tend to be pinned on TBs. Both observations demonstrate that TBs locally weaken the superconductivity in FeSe.
All STM/STS tunneling experiments presented here were carried out at 4.5 K on a commercial ultrahigh vacuum (UHV) low temperature STM apparatus (Unisoku), which is connected to an MBE system for in situ sample preparation. The base pressure for both systems is better than 10^{-10} Torr. MBE growth of stoichiometric FeSe films has been described in detail elsewhere [15, 16], and in the supplement [17]. Prior to data collection, a polycrystalline PtIr tip was cleaned by electron-beam heating in UHV, and then calibrated on an MBE-grown Ag film on a Si(111) substrate. Spectroscopic measurements were made by disrupting the feedback circuit, sweeping the sample voltage, and extracting the tunneling conductance $dI/dV$ using a standard lock-in technique with a small bias modulation of 0.1 mV at 987.5 Hz.

Figure 1(a) depicts a constant-current topographic image of the as-grown FeSe films. The localized defects ($< 0.05\%$) correspond to individual excess Se atoms [16], which are intentionally introduced and act as scatterers for electrons and give rise to unidirectional electronic nanostructures in FeSe [15]. A more detailed examination shows that each excess Se explicitly breaks four-fold ($C_4$) rotational symmetry in two independent ways, at two different length scales. First, at the atomic length scale, we observe two orthogonal dumbbell-like features (insets), labeled as $\mu$ and $\nu$. Both atomic dumbbells are centered at subsurface Fe atoms [Fig. 1(b)], with their bright ends positioned on two adjacent Se atoms in the topmost layer, suggesting that the excess Se substitutes into the uppermost Fe layer. Two inequivalent Fe positions, denoted by $\mu$ and $\nu$ in Fig. 1(d), lead to the two orthogonal atomic dumbbells observed. Second, at the much larger length scale of $\sim 16a_{Fe-Fe} \approx 4.4$ nm [Fig. 1(c)], the $C_4$ symmetry is broken by unidirectional depressions in density of states which straddle each excess Se (yellow dashes). In contrast to the persistence of atomic dumbbells up to 2.5 eV imaging bias, the larger unidirectional features exist only in a narrow energy range (approximately $\pm 20$ meV), which supports a purely electronic origin. Note that in Fig. 1(a) a faint stripe occurs along the upper left to lower right diagonal. Across this stripe, the Se-induced unidirectional nanostructures (electronic dimers) are found to rotate by 90°. This closely resembles the TB-induced 90° rotation of $\sim 8a_{Fe-Fe}$ unidirectional nanostructures in slightly Co-doped Ca(Fe_{1-x}Co_x)2As_2 [18]. We therefore argue that the observed faint stripe along the diagonal of Fig. 1(a) represents a TB, across which the $a$ and $b$ crystalline axes interchange. Here $a$- and $b$- correspond to the two Fe-Fe bonding directions, as defined in Fig. 1(e). Note that these larger electronic dimers always respect the crystalline $a$ axis, irrespective of the stochastic distribution of atomic $\mu$ and $\nu$ dumbbells. These observations not only provide a way to distinguish TBs, but also support the fundamental role that electronic dimers play in scattering mechanisms [19, 20], and by implication, transport anisotropy in iron pnictides [21].
To find the effect of TBs on superconductivity, we use STS to map the superconducting gap in the vicinity of another TB [Fig. 2(a)]. Using the atomically-resolved STM image in Fig. 2(b), we note that the TB runs nearly along one of the Se-Se nearest-neighbor directions in the topmost layer, or equivalently one diagonal of the undistorted single-Fe unit cells. Fig. 2(c) shows a series of differential conductance $dI/dV$ spectra, normalized to the normal-state conductance spectrum above $T_c$ (10 K), taken along a trajectory approaching the twin boundary. All curves exhibit superconducting gaps with clear coherence peaks. However the gap magnitude $\Delta$, half of the energy between the coherence peaks, decreases when approaching the TB, suggesting that TBs tend to weaken the superconductivity in FeSe. This is further supported by $dI/dV$ maps at zero energy [Fig. 2(d)] and at one of the coherence peaks at $\sim 2.2$ meV [Fig. 2(e)] on the same region as Fig. 2(a). The TB enhances the zero-bias conductance (ZBC, inversely correlated with the superfluid density) and suppresses the coherence peaks. Our observations consistently support the suppression of superconductivity by TBs in FeSe. This contrasts with the enhanced superfluid density along TBs in underdoped Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ by SQUID measurements as well as the recent theoretical prediction [5, 22].

Our STM images therefore demonstrate directly for the first time the coherence-length-scale effect of a TB on superconductivity in the new Fe-based superconductors.

**FIG. 4.** (color online) (a) A 150 nm $\times$ 150 nm topographic image with three TBs ($V = 10$ mV, $I = 0.1$ nA). (b) Simultaneous ZBC map showing the vortices at 2 T. Tunneling gap is set at $V = 10$ mV and $I = 0.1$ nA. (c) Schematic illustrating both TBs (white dashes) and vortices (red circles).

The suppressed superconductivity and thus reduced superfluid density along TBs should lead to a decrease in energy when vortices are positioned on TBs. To search for such TB flux pinning, we image vortices with an applied magnetic field normal to the FeSe $ab$-plane. Fig. 4(a) shows a topographic image with three TBs, where we record the ZBC map at 2 T, illustrated in Fig. 4(b). Previously, a pronounced ZBC peak, which originates from quasiparticle bound states [24, 25], has been found in the vortex cores of FeSe [15]. Therefore the yellow regions with enhanced ZBC signify individual isolated vortices. The observed average flux per vortex is $\sim 2.05 \times 10^{-15}$ Wb [17], consistent with single magnetic flux quantum, $\Phi_0 = 2.07 \times 10^{-15}$ Wb. The schematic depiction of vortices and twin boundaries in Fig. 4(c) illustrates that vortices are preferentially pinned on TBs [17] as long as the distance separating the neighboring TBs is not too large. This observation confirms that TBs locally suppress the superconductivity in FeSe.

Now we consider possible explanations for the suppressed superconductivity by TBs in FeSe. Variation in chemical doping across TBs can be reasonably excluded [13] because the superconductivity develops in FeSe without any external doping, in sharp contrast to iron pnictides [26]. We thus consider that the phenomenon likely stems from the structural changes around TBs. Indeed, in iron-based superconductors, the tetrahedral geometry, both the tetrahedral angle $\alpha$, and...
the anion-height $h_{\text{anion}}$ (pnnictogen or chalcogen) above the Fe layer, appear to be key parameters controlling the superconducting transition temperature $T_c$. For each FeSe$_4$ tetrahedron spanning a TB, two out of four Se anions must be mirror-symmetric with respect to the twinning plane [Fig. 1(e)], which will distort the FeSe$_4$ tetrahedra and thus change $\alpha$. However, some previous studies have demonstrated that $\alpha$ does not significantly affect $T_c$ in iron chalcogenides [27, 28]. We therefore suggest that the tetrahedral distortion cannot bear sole responsibility for the observed suppression of superconductivity around TBs in FeSe. Then we examine the Se height $h_{\text{Se}}$ around TBs. High-pressure electrical resistivity measurements revealed an enhanced $T_c$ as $h_{\text{Se}}$ is reduced [29]. In all our topographic images, up to 1 eV [17], TBs appear brighter than surrounding areas. This consistency over wide energy range strongly suggests a local increase in $h_{\text{Se}}$, although an electronic effect leading to the false appearance of increased height due to the STM normalization artifact cannot be completely ruled out.

We therefore suggest that superconductivity is suppressed and perhaps even quenched by the increased $h_{\text{Se}}$ at the TB. The well-identified superconducting gaps near TBs [Fig. 2(c)] may arise from the proximity effect between on- and off-TBs regions.

Finally, we tentatively explain the contrasting roles of TBs in Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ and FeSe. As has been noted previously, $T_c$ of the iron-based superconductors appears to reach maximum at $h_{\text{anion}} \sim 1.38$ Å [26, 29, 30]. Away from this value, $T_c$ will abruptly decrease. In FeSe, $h_{\text{Se}} \simeq 1.45$ Å > 1.38 Å [29], so the increased $h_{\text{Se}}$ must suppress $T_c$ at TBs. However, in Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$, $h_{\text{As}} \simeq 1.34$ Å appears smaller than 1.38 Å [31]. Assuming that $h_{\text{As}}$ increases around TBs of Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ as well, one can expect enhanced superfluid density there, in line with SQUID experiments [5, 6]. Moreover, $h_{\text{anion}}$ may play a more important role in FeSe than in Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$. The increased $h_{\text{Se}}$ at FeSe TBs favors the double-stripe $(\pi, 0)$ magnetic order, and suppresses the $(\pi, \pi)$ spin fluctuations which are necessary for superconductivity [32]. The present study therefore provides evidence linking $h_{\text{anion}}$ to local $\Delta$ and thus to the mechanism of superconductivity in iron-based compounds.

Our detailed STM/STS study of TBs in MBE-grown FeSe films has provided fundamental new information on the nature of superconductivity in iron-based materials. First, we have explicitly shown by direct imaging that each Fe-site impurity produces a local electronic dimer of size $\sim$ 16a$_{\text{FeFe}}$, oriented along the orthorhombic $\alpha$-axis. Scattering from these dimers, although never previously directly visualized in real space, has been controversially suggested as the root cause of the transport anisotropy in iron-based superconductors [19, 20]. Second, we have shown by spatially resolved spectroscopy that TBs suppress the superconductivity within a superconducting coherence length $\xi$. This provides a quantitative measure of the coherence length, $\xi \sim 5.1$ nm. Third, we show that magnetic vortices are preferentially pinned to the TBs. This supports the suppression of superconductivity at the TBs, and can inform engineering work to optimize vortex pinning for increased critical current. Finally, we show increased $h_{\text{Se}}$ at the FeSe TBs. This suggests an explanation for the contrast between TB behavior in FeSe vs. Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$, and indeed provides the first local evidence for the importance of chalcogen/pnictogen height $h_{\text{anion}}$ to the very nature of the superconducting mechanism in iron-based materials.
