(Dated: August 24, 2012)

Resonating valence bond (RVB) states are of crucial importance in our intuitive understanding of quantum spin liquids in two dimensions (2D). We systematically classify short-range RVB states into symmetric or nematic spin liquids, by examining their flux patterns. We further map short-range RVB states into projected BCS wave functions, on which we perform large-scale Monte Carlo simulations without the minus sign problem. Our results clearly show that both spin and dimer correlations decay exponentially in all the short-range frustrated RVB states we studied, indicating that they are gapped $Z_2$ quantum spin liquids. Generically, we conjecture that all short-range frustrated RVB states in 2D have short-range correlations.

Introduction: Quantum spin liquids are exotic insulators which cannot be adiabatically connected into a band insulator and which can support fractionalized excitations\cite{1}. Introduced by Anderson nearly four decades ago\cite{2}, the resonating valence bond (RVB) state on the triangular lattice is the first example of quantum spin liquids in more than one dimension. Since then, there have been keen interest of searching for such exotic states of matter in real materials as well as in microscopic models, especially after exciting connections between quantum spin liquids and the mechanism of high temperature superconductivity were suggested\cite{3–5}.

Recently, there is a surge of numerical simulations on simple models reporting convincing evidence of the existence of fully gapped spin liquids\cite{6–11}, all of which are believed to be in the same class of short-range RVB states. Nonetheless, the nature of short-range RVB states on various frustrated lattices has not been revealed\cite{12, 13}, mainly because of the so-called minus sign problem in Monte Carlo (MC) simulations of those bosonic short-range RVB states with frustration. Due to their conceptual importance in pictorially understanding quantum spin liquids and their direct relevance in recent numerical simulations, it is highly desired to unambiguously demonstrate the nature of these short-range bosonic RVB states.

In this paper, we systematically classify short-range RVB states by examining their flux patterns\cite{14}. For instance, for the Kagome lattice we establish that there are only four symmetric and four nematic RVB states when considering only nearest-neighbor (NN) valence bonds as shown in Fig. 1 and 5(a) respectively. Then, we show that these bosonic short-range RVB states can be exactly mapped into projected BCS wave functions\cite{17–19} on which we perform large-scale MC simulations without the minus sign. For frustrated short-range RVB states, our simulations on corresponding projected BCS states convincingly show that both their spin and dimer correlations decay exponentially, indicating that they are fully gapped $Z_2$ spin liquids\cite{20, 21}.

Bosonic RVB states: We consider the following bosonic RVB states with NN and possibly next-nearest-neighbor (NNN) valence bonds

$$\psi_{\text{RVB}} = \sum_c |c\rangle, \quad |c\rangle = (-1)^{\delta_c} \prod_{(ij)\in c} f_{ij} |ij\rangle, \quad (1)$$

where $c$ labels valence bond configurations and $\delta_c$ represents the number of bond-crossings in $c$ [the factor $(-1)^{\delta_c}$ is nontrivial only for RVB states with valence bonds beyond nearest-neighbor sites]. Here $|ij\rangle \equiv (|\uparrow_i\downarrow_j\rangle - |\downarrow_i\uparrow_j\rangle)/\sqrt{2}$ is the spin-singlet wave function (or valence bond) on $(ij)$ and we assume $f_{ij}$ to respect all the lattice symmetries. Note that Eq. (1) represents a “bosonic” RVB state in the sense that $|\uparrow_i\downarrow_j\rangle = |\downarrow_j\uparrow_i\rangle$. Since $|ij\rangle = -|ji\rangle$, it is sufficient to consider $f_{ij} = -f_{ji}$. The wave function in Eq. (1) possesses a gauge symmetry: $|\psi_{\text{RVB}}\rangle$ is invariant, up to a phase, under the transformation $f_{ij} \rightarrow e^{i\alpha_j} f_{ij} e^{i\alpha_i}$. In the following, we focus on time reversal invariant RVB states for which all $f_{ij}$ are real; signs of $f_{ij}$ can be represented by oriented arrows on graphs: an arrow pointing from $i$ to $j$ means that $f_{ij} > 0$, as shown in Fig. 1. We further define flux $\phi_p = 0, \pi$ (mod $2\pi$) for plaquette $p$ through

$$\prod_{(jk)\in p} \text{sgn}(f_{jk}) = \exp(i\phi_p) \quad (2)$$

where $cc$ means that the counterclockwise order of $(jk)$ is taken in the product above and sgn is the sign function. It is clear that $\phi_p$ is invariant for even-length plaquette $p$. However, the gauge transformation with $\exp(i\alpha_j) = i$ on every site $j$ changes $\phi_p$ to $\phi_p + \pi$ for all odd-length plaquette $p$. In other words, the two wave functions with flux pattern $\{\phi_p\}$ and $\{\phi_p + (-1)^{n_p}\pi\}$ ($n_p$ is the length of plaquette $p$) actually represent the same state\cite{22}.

There are two questions concerning the wave function in Eq. (1) to be answered. First, is it a symmetric spin liquid respecting all the symmetries of the lattice in question? Second, do various correlations decay in power law
FIG. 1: (a) The flux patterns \{φ_p\} of the only four symmetric NN-RVB states on the Kagome lattice. Here \(e_x\) and \(e_y\) represent the unit vectors. (b) The flux patterns \{φ'_p\} in the corresponding projected BCS states.

or exponentially? The first question can be answered by examining its flux pattern \{φ_p\}. If the flux pattern \{φ_p\} is invariant up to the addition of \((-1)^{n_p}π\), under all lattice symmetry transformations such as translations, rotations, and reflections, the corresponding RVB state is then a symmetric spin liquid state. We label RVB states with longest valence bonds between NN (NNN) sites as frustrated RVB states. Frustrated RVB states include NN-RVB states on frustrated lattices (e.g. the triangular and Kagome lattices), NNN-RVB states on the square lattice, and the \{φ_p = 0\} NN-RVB state on the square lattice. It is clear that loop-algorithm MC simulations on frustrated RVB states suffer from the minus sign problem in the variational level. In the following, we shall show that the RVB states in Eq. (1) can be exactly mapped into Gutzwiller projected BCS states, which are friendly to MC simulations without the minus sign problem.

Projected BCS states: It was known that variational Monte Carlo method has been quite successful in simulating Gutzwiller projected BCS wave functions. We consider the following projected BCS wave functions:

\[
|\psi_{\text{p-BCS}}\rangle = \mathcal{P}_G \exp \left[ \sum_{i<j} g_{ij} \left( c_{i\sigma}^{\dagger} c_{j\sigma}^{\dagger} - c_{i\sigma}^{\dagger} c_{j\sigma}^{\dagger} \right) \right] |0\rangle,
\]

where \(c_{i\sigma}^{\dagger}\) are electron creation operators, \(|0\rangle\) is the vacuum, \(\mathcal{P}_G\) is the Gutzwiller projection onto singly occupied states, and \(g_{ij} = g_{ji}\) which are assumed to be real. A similar gauge symmetry exists for the projected BCS wave functions: the wave function is invariant, up to a phase, under the transformations: \(g_{jk} \rightarrow \exp(iα_j^f)g_{jk} \exp(iα_k^f)\). For time reversal invariant states with real \(g_{jk}\), we define fermionic fluxes \(φ_p^f\) through \(\prod_{(jk)\in P} \text{sgn}(g_{jk}) = \exp(iα_j^f)\) with \(φ_p^f = 0, π\) (mod 2π). Similarly, the flux pattern \{φ'_p\} and \{φ'_p + (-1)^{n_p}π\} are equivalent through the gauge transformation \(\exp(iα_j^f) = i\) on all sites \(j\). As shown in details in the Appendix, we obtain \(|\psi_{\text{p-BCS}}\rangle = |\psi_{\text{RVB}}\rangle\) when the following conditions are satisfied:

\[
|g_{jk}| = |f_{jk}|, \quad φ_p = φ'_p + π,
\]

where \(p\) labels all possible elementary plaquettes.

Ground state correlations: We have investigated a number of short-range frustrated RVB states by performing MC simulations on their corresponding projected BCS wave functions. In our numerical calculations, we mainly focus on spin as well as dimer correlations and study whether they fall off in power law or exponentially at large distance. The spin and dimer correlations are

TABLE I: The spin (ξ_s) and dimer (ξ_d) correlation lengths of the four symmetric states on the Kagome lattice shown in Fig. 1. Here E labels the variational energy per site of these symmetric states for the Kagome NN antiferromagnetic Heisenberg model \(H = J \sum_{\langle ij\rangle} S_i \cdot S_j\).
where \( e \equiv (\vec{r}_i + \vec{r}_{i+1})/2 \), respectively] for all the four symmetric NN-RVB spin liquids are related by one elementary flip. In the counterclockwise-clockwise NN-RVB state (A) shown in Fig. 1. The MC calculations are carried out on a lattice with 18 x 18 x 3 sites and with periodic boundary conditions. It is remarkable that the correlations decay extremely fast. From Fig. 4, it is clear that both spin and dimer correlations decay exponentially in distance. The spin correlation length \( \xi_s \) for this NN-RVB state is about 0.6 lattice constants. The dimer correlation lengths \( \xi_{d,x} \) and \( \xi_{d,y} \) for \( D_x(e_x) \) and \( D_y(e_y) \) are nearly equal, which are about 1.2 lattice constants. The spin and dimer correlation lengths \( [\xi_s = (\xi_{d,x} + \xi_{d,y})/2] \), respectively] for all the four symmetric NN-RVB spin liquids are listed in Table I. The correlation lengths are all in the order of one lattice constant, indicating that they are fully gapped.

\[ S(\bar{l}) = \left( \mathbf{S}_{\vec{r}_i} \cdot \mathbf{S}_{\vec{r}_{i+1}} \right), \]
\[ D_\alpha(\bar{l}) = \left( \left( \mathbf{S}_{\vec{r}_i} \cdot \mathbf{S}_{\vec{r}_{i+1}+e_\alpha} \right) \left( \mathbf{S}_{\vec{r}_{i+1}} \cdot \mathbf{S}_{\vec{r}_i+e_\alpha} \right) \right)^2, \]

where \( e_\alpha \) labels lattice vectors.

We have studied all the four symmetric NNN-RVB states on the square lattice, the four symmetric NN-RVB states on the Kagome lattice, and the two symmetric NN-RVB states on the triangular lattice. As discussed in details later, for all these frustrated RVB states our MC simulations convincingly show that their spin and dimer correlations fall off exponentially with correlation length in the order of one lattice constant, indicating that they are all gapped \( Z_2 \) quantum spin liquids. (Note that different symmetric spin liquid states on the same lattice may be distinguished by numerically computing local correlations.) We conjecture that our results are generic: all frustrated short-range RVB states in 2D are fully gapped.

**The Kagome lattice**: According to the flux pattern (either \( \{ \phi_p \} \) or \( \{ \phi_p^{1/2} \} \)) on the Kagome lattice, it is straightforward to show that there are four symmetric NN-RVB spin liquids, as shown in Fig. 1. We have computed the spin and dimer correlations for all the four symmetric NN-RVB spin liquids. In Fig. 4, we plot the spin and dimer correlations as a function of distance \( \bar{l} \) in one of those NN-RVB symmetric states, i.e. the counterclockwise-clockwise NN-RVB state (A) shown in Fig. 1. The MC calculations are carried out on a lattice with 18 x 18 x 3 sites and with periodic boundary conditions. It is remarkable that the correlations decay extremely fast. From Fig. 4, it is clear that both spin and dimer correlations decay exponentially in distance. The spin correlation length \( \xi_s \), for this NN-RVB state is about 0.6 lattice constants. The dimer correlation lengths \( \xi_{d,x} \) and \( \xi_{d,y} \) for \( D_x(e_x) \) and \( D_y(e_y) \) are nearly equal, which are about 1.2 lattice constants. The spin and dimer correlation lengths \( \xi \) and \( \xi_d \equiv (\xi_{d,x} + \xi_{d,y})/2 \), respectively] for all the four symmetric NN-RVB spin liquids are listed in Table I. The correlation lengths are all in the order of one lattice constant, indicating that they are fully gapped \( Z_2 \) quantum spin liquids. This is consistent with the recent DMRG evidence that the ground state of the Kagome Heisenberg antiferromagnet is a fully gapped quantum spin liquid[8, 9] with correlation lengths of about one lattice spacing[9].

To get a sense which state above is the best variational wavefunction for the Kagome antiferromagnet described by \( H = J \sum_{\langle ij \rangle} S_i \cdot S_j \), we compute their variational energy per site as shown in Table I. Among the four symmetric NN-RVB spin-liquid states, the counterclockwise-clockwise NN-RVB state has the lowest energy for the Kagome antiferromagnet, which is \(-0.393J\) per site. This energy still differs from the DMRG result, indicating that longer-range valence bonds are important in describing the Kagome antiferromagnet.

**The triangular lattice**: It turns out that there are only two symmetric NN-RVB spin liquid states on the triangular lattice, whose flux patterns \( \{ \phi_p \} \) are shown in Fig. 2. For both states, the spin and dimer correlations decay exponentially with distance, with \( \xi_s = 0.7 \) and \( \xi_d = 1.0 \) for the state (A) shown in Fig. 2 and \( \xi_s = 1.0 \) and \( \xi_d = 1.6 \) for the state (B) shown in Fig. 2. Both NN-RVB states are then gapped \( Z_2 \) spin liquids. The correlation lengths on the triangular lattice are somewhat longer than those on the Kagome lattice, which is expected due to more geometric frustrations in the Kagome lattice.

**The square lattice**: It was shown recently that the unfrustrated NN-RVB state on the square lattice is a critical state with power-law dimer correlations even though its spin excitations are gapped[26, 27]. To have a fully gapped spin liquid phase on this lattice, it is necessary to include frustration in short-range RVB states. One candidate is the frustrated NN-RVB state with \( \{ \phi_p = \pi \} \), called negative RVB in Ref. [28], in which \( \langle c|c' \rangle < 0 \) when \( c \) and \( c' \) are related by one elementary flip. In
this paper, we consider the other choice, namely including NNN valence bonds, which is partly motivated by a recent study establishing that fully gapped spin liquid ground states are realized in the generalized \[29\] quantum dimer models\[30\] with NN and NNN dimers on the square lattice. (Note that the nature of NNN RVB states in Eq. (1) without the factor \((-1)^{bc}\) remains unknown due to the lack of mapping between them and projected BCS states.)

From the flux pattern \(\{\phi_p\}\), we have identified four symmetric NNN-RVB states on the square lattice, as shown in Fig. 3(b). For each of these four states, there is an additional parameter labeling the wave function, namely the ratio \(\gamma \equiv |f_{\text{NN}}|/f_{\text{NN}}|\). We take \(\gamma = 1\) in our MC simulations. For \(\gamma = 1\) both spin and dimer correlations decay exponentially with distance. The correlation lengths are listed in Table II, where \(\xi_{\text{d,NN}}\) and \(\xi_{\text{d,NNN}}\) mean the correlation lengths of NN and NNN dimers, respectively. At \(\gamma = 1\) (more generally \(\gamma > 0\)), we conclude that the four symmetric NNN-RVB states are fully gapped \(Z_2\) spin liquids, which is consistent with the recent numerical evidence of fully gapped spin liquids in the \(J_1-J_2\) square Heisenberg antiferromagnet\[10, 11\]. The variational energies of these NNN-RVB states in unit of \(J_1\) for the \(J_1-J_2\) square Heisenberg model with \(J_2 = J_1/2\) are shown in Table II.

Nematic RVB spin liquids: We have studied fully symmetric short-range RVB spin liquids on various lattices. An interesting question is whether short-range RVB states could be nematic spin liquids which are translationally invariant but break lattice point group symmetry. The answer is yes. On the Kagome lattice, we identified that there are only four NN-RVB states which are nematic spin liquids, as shown in Fig. 5(a). On the triangular lattice, there are two nematic NN-RVB states, as shown in Fig. 5(b). Our MC simulations show that the correlation functions of spins and dimers in these states decay exponentially with distance but the \(C_6\) symmetry of both lattices is broken. They are fully gapped nematic spin liquids, in contrast with gapless nematic spin liquids on the triangular lattice studied in Ref. \[31\].

On the square lattice, we found six nematic NNN-RVB spin-liquid states, which are shown in Fig. 5(c). These spin-liquid states keep the translational symmetry but breaks the \(C_{4v}\) rotational symmetry of the square lattice. Again, our MC simulations show that they are fully gapped nematic spin liquids.

**Concluding discussions:** On the square (or honeycomb) lattice, there are two kinds of symmetric NNN-RVB spin-liquids. The \(\{\phi_p = 0\}\) NN-RVB state is unfrustrated with power-law decaying dimer correlations\[26, 27\]. While the \(\{\phi_p = \pi\}\) NN-RVB state is frustrated, our MC simulations on the square lattice with \(20 \times 20\) sites cannot tell whether its dimer correlation decays exponentially or in power law. Studies on larger lattices are necessary in the future to identify its nature. Nonetheless, we conjecture that all short-range 2D frustrated RVB states exhibit only short range correlations.

A recent loop-algorithm MC study shows that the unfrustrated NN-RVB states on the cubic and diamond lattices show magnetic long-range order\[32\]. Properties of frustrated NN-RVB states on 3D lattices remain unknown partly due to the minus sign problem in loop-algorithm MC simulations. We can generalize the mapping between short-range RVB states and projected BCS states discussed in the present paper to three dimensions. Consequently, we can solve the minus sign problem for a class of frustrated short-range RVB states, which is a significant step towards understanding the nature of short-range frustrated RVB states in 3D.

We are grateful to Zheng-Yu Weng and Tao Xiang for sharing computing resources and thank Steve Kivelson and Tao Li for helpful discussions. This work is supported in part by NSFC under grants 10704008 and 11274041 (FY), and by Tsinghua Startup Funds and NSF grant DMR-0904264 (HY). Note added: After the completion of the present work, we notice the paper by J. Wildeboer and A. Seidel studying topics, partly overlapping with the present paper, but from seemingly different approaches\[33\].

---

**FIG. 4:** The spin and dimer correlations as a function of distance in the NN-RVB state (A) shown in Fig. 1.

**FIG. 5:** The flux patterns \(\{\phi_p\}\) of (a) the four nematic NN-RVB states on the Kagome lattice, (b) the two nematic NN-RVB states on the triangular lattice, and (c) the six nematic NNN-RVB states on square lattice.
It's now known that for antiferromagnetic Heisenberg models on the triangular (or square) lattice with only nearest-neighbor couplings, their ground states have magnetic orders.

Note that the definition of fluxes above for time reversal invariant RVB states with real $f_{ij}$ is consistent with the more general one on even-length plaquettes studied in Refs. [16, 23].

[14] The classification here might be closely related to studies based on the projective symmetry group in Ref. [15, 16].
[22] Note that the definition of fluxes above for time reversal invariant RVB states with real $f_{ij}$ is consistent with the more general one on even-length plaquettes studied in Refs. [16, 23].
