(Dated: September 7, 2012)

We show that quantum frequency conversion (QFC) can overcome the spectral distinguishability common to inhomogeneously broadened solid-state quantum emitters. QFC is implemented by combining single photons from an InAs quantum dot (QD) at 980 nm with a 1550 nm pump laser in a periodically-poled lithium niobate (PPLN) waveguide to generate photons at 600 nm with a signal-to-background ratio exceeding 100:1. Photon correlation and two-photon interference measurements confirm that both the single photon character and wavepacket interference of individual QD states are preserved during frequency conversion. Finally, we convert two spectrally separate QD transitions to the same wavelength in a single PPLN waveguide and show that the resulting field exhibits non-classical two-photon interference.

Quantum frequency conversion (QFC) [1] is a potentially crucial resource in interfacing photonic quantum systems operating at disparate frequencies. Such a hybrid quantum system could, for example, combine robust and stable quantum light sources based on solid-state emitters [2] with broadband quantum memories based on dense atomic ensembles [3] to enable entanglement distribution in a long-distance quantum network [4]. QFC has been enabled by the development of high-efficiency frequency conversion techniques [5, 6], and been demonstrated in experiments showing that the quantum character of a light field was preserved during the process [7–13]. In particular, recent experiments have focused on QFC of single photon states, with both frequency up-conversion [10, 11] and downconversion [12, 13] of triggered [10, 13] and heralded [11, 12] sources shown. QFC can be particularly valuable for solid-state quantum emitters, as prominent systems like semiconductor quantum dots [2] and nitrogen vacancy centers in diamond [14] exhibit significant inhomogeneous broadening. Thus, although these systems are in principle scalable, applications which require identical quantum light sources need a mechanism to bring spectrally disparate sources into resonance [15–19]. Unlike previous demonstrations, in which techniques such as strain/optical/electric fields were applied, QFC can fulfill this role [20] without requiring direct modification of the sources themselves.

Here, we demonstrate nearly background-free QFC, which we use to enable experiments examining photon statistics and two-photon interference of single photons from a semiconductor quantum dot. Compared to previous telecommunications (1300 nm) to visible (710 nm) conversion [10], we work with quantum dots (QDs) emitting in the well-studied 900 nm to 1000 nm wavelength range [2], and convert their single photon emission to 600 nm, a wavelength region in which Si single photon avalanche diodes (SPADs) offer a combination of quantum efficiency and timing resolution that is currently unavailable in the 980 nm band [21]. Using a much wider wavelength separation between signal and pump photons improves the signal-to-background level by about two orders of magnitude with respect to Ref. 10. Measurements of photon statistics and two-photon interference before and after conversion indicate no degradation in purity or wavepacket overlap of the single photon stream due to the frequency conversion process. Finally, we show that two spectrally separate transitions of a QD can be converted to the same wavelength in a single PPLN waveguide, and present initial measurements demonstrating two-photon interference of these frequency-converted photons. This represents a first step towards a resource-efficient approach in which a single nonlinear crystal acts as a QFC interface that generates indistinguishable photons from different solid-state sources [22].

The basic experimental system is depicted in Fig. 1(a) and described in detail in the Supplemental Information [23]. Our single photon source is an InAs QD in a fiber-coupled, GaAs microdisk optical cavity [24] excited by a continuous wave (cw) or pulsed (50 MHz repetition rate, 50 ps pulse width) 780 nm laser diode. Spectrally isolated emission from the QD can be studied in the 980 nm band through photon correlation and two-photon interference (Hong-Ou-Mandel [25]) measurements, or else sent to the frequency conversion setup. Frequency conversion is done by combining a strong, tunable 1550 nm pump laser with the 980 nm QD signal and coupling them into a PPLN waveguide. The 600 nm converted signal is spectrally isolated from frequency-doubled pump light through prisms and short-pass filters, and sent into either a second photon correlation or Hong-Ou-Mandel apparatus, to study the photon statistics and two-photon interference after frequency conversion.
FIG. 1. (a) Experimental setup used within this work [23]. HBT = Hanbury-Brown and Twiss setup; HOM = Hong-Ou-Mandel interferometer. (b) Converted 600 nm band wavelength vs. PPLN waveguide temperature. The inset shows the quasi-phase-matching response of the PPLN waveguide. (c) Signal-to-background ratio (left y-axis, blue points) and external conversion efficiency (right y-axis, red points) as a function of 1550 nm pump power. The external conversion efficiency includes all losses in the system.

We characterize the frequency conversion setup [23] using an attenuated (∼30 fW) 980 nm band laser. First, we measure the quasi-phase-matching bandwidth of the PPLN waveguide, and find that it follows the expected sinc² response [5] with an inferred bandwidth in the 980 nm band of ∼0.20 nm (inset of Fig. 1(b)). Next, we study how the frequency converted wavelength changes with PPLN waveguide temperature, which influences phase-matching through thermo-optic and thermal expansion contributions. The resulting plot in Fig. 1(b) indicates that the output wavelength can be tuned by ∼2 nm. We have also found that signals between 970 nm and >995 nm can be converted (>35% external conversion efficiency) by appropriately adjusting the 1550 nm wavelength and PPLN waveguide temperature. This covers the s-shell emission range of the QD ensemble, and means that QDs emitting at different wavelengths (unavoidable due to size/shape/composition dispersion during growth) can be converted to the same wavelength.

Ideally, QFC should avoid generating noise photons that are spectrally unresolvable from the frequency-converted quantum state. Sum- and difference-frequency generation in χ(2) materials are background-free in principle [1], meaning that signal photons are directly converted to idler photons without amplifying vacuum fluctuations. However, other processes, such as frequency conversion of broadband Raman-scattered pump photons, may still be a source of noise, as observed in experiments using PPLN waveguides [26]. To quantify this, the signal-to-background ratio of the converted signal is measured, and reveals the fraction of converted photons originating from the signal rather than noise processes. In previous work [10], the signal-to-background was limited to 7:1, and though use of a pulsed pump removed temporally distinguishable background noise [27], it did not improve the signal-to-background level. While better spectral filtering provides improvement (>10:1 signal-to-background was reported recently [13]), it is perhaps more desirable to suppress the noise source, for example, by increasing the separation between the signal and red-detuned pump [26, 28, 29]. Here, our pump-signal separation is nearly 600 nm, suggesting potentially significant improvement.

To test this, we measure (Fig. 1(c)) the signal-to-background level by spectrally isolating the 600 nm conversion band [23] and comparing the detected counts on the SPAD with and without the presence of the 980 nm band signal (the SPAD dark count rate of ∼50 s⁻¹ is subtracted to give a detector-independent metric). We also plot the external conversion efficiency, which includes all PPLN input/output coupling, free-space transmission, and spectral filtering losses (detector quantum efficiency is not included). The signal-to-background level remains above 100 for all but the highest 1550 nm pump powers, where the conversion efficiency has begun to roll off. For the experiments that follow, we operate with a 35% to 40% external conversion efficiency and a signal-to-background level >100. As the PPLN incoupling efficiency is ∼60%, and the transmission through all optics after the PPLN waveguide is ∼80%, the internal conversion efficiency in the PPLN waveguide is ∼70%.

We now present measurements combining frequency conversion with QD-based single photon sources. We study three devices, M1, M2, and M3, under pulsed and cw excitation conditions. Pulsed measurements are a convenient way to judge the temporal distribution of noise photons produced in the conversion process. Fig-
FIG. 3. (a) Auto-correlation of the X1 emission line from device M2 under cw excitation (µ-PL spectrum inset). (b) and (c) Two-photon interference of the X1 line under parallel and orthogonal polarization configurations of the interferometer arms, respectively. (d) Auto-correlation of the X1 line after frequency conversion (frequency converted spectrum inset). (e) and (f) Two-photon interference of the frequency converted X1 line under parallel and orthogonal polarization configurations of the interferometer arms, respectively. The dashed lines are fits to the experimental data [23], and the solid line marks $g(2)(0) = 0.5$ level.

Two photon interference as $V = (g(2)(0) - 1)/g(2)(0)$ stems from the non-zero value of $g(2)(0)$ (Fig. 3(a)) and $g(2)(0)$ again show that single photon nature of X1 emission is conserved through the frequency conversion process. In many cases, both single photon purity and single photon indistinguishability [30] are important. At the heart of indistinguishability measurements is two-photon interference [25], which we now show is preserved in our frequency conversion process. Two-photon interference under cw excitation was performed using a fiber-based Mach-Zehnder interferometer [23] similar to Refs. [31, 32], where one interferometer arm contains a 12.5 ns delay and a polarization rotator. Rotating the polarization of photons from this arm that are incident on the second beamsplitter of the Mach-Zehnder reveals the effect of interference on the photon correlations. In the orthogonal polarization configuration, the interferometer arms are distinguishable and $g(2)(0) = 0.5$ for a pure single photon source. On the other hand, in the parallel polarization configuration, one expects interference between the photons within their coherence time, leading to $g(2)(0) = 0$. Figures 3(b) and (c) show the results of experiments on the X1 emission line after frequency conversion. The antibunching values are $g(2)(0) = 0.35 ± 0.03$ and $g(2)(0) = 0.52 ± 0.04$, yielding the visibility of two-photon interference as $V = (g(2)(0) - g(2)(0))/g(2)(0) = 0.33 ± 0.08$. The deviation from the ideal value of $V = 1$ stems from the non-zero value of $g(2)(0)$ (Fig. 3(a)) and the time resolution of the photon correlation setup that is on the order of the coherence time ($≈ 100$ ps) of the QD emission [32]. The same experiments were performed on the X1 emission line after frequency conversion, and Figs. 3(e) and (f) show the results for parallel and orthogonal polarization configurations, respectively ($g(2)(0) = 0.36 ± 0.02$, $g(2)(0) = 0.53 ± 0.04$). Due to the conservation of the QD coherence time during the frequency conversion process, we observed a similar two-photon interference visibility $V = 0.32 ± 0.06$ at 600 nm.

As discussed earlier, a wide wavelength range of QD emission within the 980 nm band can be efficiently converted to 600 nm by controlling the temperature of the PPLN waveguide and the wavelength of the 1550 nm pump laser. This enables the conversion of well-separated emission lines to the same wavelength at 600 nm. To demonstrate this, both bright emission lines X1 and X2 from device M2 (µ-PL spectrum repeated in Fig. 4(a))
are directed to the frequency conversion setup [23], together with two 1550 nm cw pump lasers whose wavelengths are optimized for efficient conversion of the two 980 nm band signals (which are separated by ≈ 0.5 nm). Figure 4(c) shows the PL spectrum of the total converted signal at 600 nm, where the converted signals of the individual X1 and X2 lines are spectrally overlapped (within the spectrometer’s resolution ≈ 40 μeV).

To better understand the nature of the measured emission lines, a cross-correlation measurement was performed before frequency conversion, where the spectrally filtered X1 and X2 lines were sent to the stop and start channels of the HBT setup, respectively. As shown in Fig. 4(b), a strong asymmetric antibunching dip is observed with \( g^{(2)}(0) = 0.26 \pm 0.02 \). The antibunching shows that both emission lines originate from the same QD, while the asymmetry is related to the radiative dynamics within the QD. The faster recovery time for \( \tau > 0 \) can be explained if X1 and X2 arise from neutral and charged excitonic emission, respectively [33]. This effect arises because emission of the charged exciton X2 leaves the QD with a single charge, so that subsequent emission in the neutral exciton state X1 requires capture of only a single (opposite) charge. This yields a much faster recovery time than that needed to obtain three charges in the QD, which sets the recovery time for \( \tau < 0 \).

Next, autocorrelation was performed on the total converted signal at 600 nm, the result of which is shown in Fig. 4(d). As expected, a strong antibunching dip with \( g^{(2)}(0) = 0.24 \pm 0.02 \) is observed. In contrast to the cross-correlation measurement before conversion, the antibunching dip now has a symmetric shape. This arises from the fact that both QD states were converted within a single PPLN waveguide, so that in the subsequent HBT measurement, the start and stop channels are fed by the same signal at 600 nm, which was composed of both X1 and X2 emission lines. This mixing of the signals going into the start and stop channels removes the asymmetry observed in the cross-correlation measurement before frequency conversion (Fig. 4(b)).

Finally, we consider two-photon interference from two spectrally distinct QD transitions, as a preliminary step towards using QFC to generate indistinguishable photons from different QDs, which has recently been shown through direct tuning of one of the QD transitions [15, 16]. We work with device M3, whose spectrum is shown in Fig. 5(a), and which was chosen because the two excitonic states X1 and X2 have relatively similar intensities. Cross-correlation measurements [23] similar to those described above were performed to confirm that both states come from the same QD. After this, the two states were converted to the same 600 nm wavelength as above, and the combined frequency converted signal was sent into a Mach-Zehnder interferometer similar to that used earlier. Data from the parallel polarization configuration is shown in Fig. 5(b)-(c), where the effect of interference on the photon correlations is seen in the narrow dip at zero time delay, which reaches a value of \( g^{(2)}_{\perp}(0) = 0.13 \pm 0.04 \). In comparison, the minimum calculated value (assuming a pure single photon source and infinite timing resolution) for the orthogonal (non-interfering) polarization configuration in our setup [23] is \( g^{(2)}_{\parallel}(0) = 0.36 \). This is smaller than the typical value of 0.5 [32] due to the delay \( \Delta \tau = 2.2 \) ns between the interferometer arms, which is comparable to the average radiative lifetime \( T_1 = 1.7 \) ns.
of the two states. Taking into account the non-zero value $g(2)(0) = 0.10$ and the finite timing resolution of the setup, $g(2)(0) = 0.45 \pm 0.04$ is estimated [23], far exceeding the measured value $g_{\perp}(2)(0) = 0.13 \pm 0.04$, and indicating the significant effect of two-photon interference from the two frequency-converted QD states.

In summary, we have demonstrated background-free quantum frequency conversion of single photons emitted from a quantum dot. Photons at 980 nm are converted to 600 nm with a signal-to-background larger than 100 and external conversion efficiency of 40%. We confirm that single photon purity and wavepacket interference are preserved during frequency conversion, and demonstrate that spectrally distinct QD emission lines can be converted to the same wavelength in the PPLN waveguide. The ability to use a single frequency conversion unit to erase spectral distinguishability in solid-state quantum emitters can be valuable in the development of scalable, chip-based photonic quantum information devices.
