A field theory of the Anderson transition in two dimensional disordered systems with spin-orbit interactions and time-reversal symmetry is developed, in which the proliferation of vortex-like topological defects is essential for localization. The sign of vortex fugacity determines the  $Z_2$  topological class of the localized phase. There are two distinct fixed points with the same critical exponents, corresponding to transitions from a metal to an insulator and a topological insulator respectively. The critical conductivity and correlation length exponent of these transitions are computed in a  $N = 1 - \epsilon$  expansion in the number of replicas, where for small  $\epsilon$  the critical points are perturbatively connected to the Kosterlitz Thouless critical point. Delocalized states, which arise at the surface of weak topological insulators and topological crystalline insulators, occur because vortex proliferation is forbidden due to the presence of symmetries that are violated by disorder, but are restored by disorder averaging.

Topology can have a profound impact on Anderson localization in disordered electronic systems. This was first understood in the integer quantum Hall effect[1, 2], where the two dimensional (2D) bulk states at the plateau transition are extended, even in the presence of strong disorder. Subsequently it was recognized that topological insulators (TI) exhibit boundary states that similarly remain extended in the presence of time reversal (TR) invariant disorder[3–5]. In the field theory of localization, this delocalization is associated with the presence of topological terms in the nonlinear  $\sigma$  model (NL $\sigma$ M)[6–10].

A shortcoming of the conventional scaling theory of localization[11–14] is that it involves only a single parameter, the conductivity. It can't distinguish the trivial insulator from the TI, and it does not explain the metallic phase that generically occurs between them[15–17]. A related difficulty is revealed by recent studies of surface states of 3D *weak* TIs (WTI)[18–20] and of topological crystalline insulators (TCI)[21, 22]. General arguments, as well as numerics, suggest that these surfaces remain delocalized even with strong disorder, due to symmetries that are violated by disorder, but remain unbroken on average. This led to the suggestion that there should be a second symmetry breaking parameter in the scaling theory[19]. This poses the question of how average symmetries fit into the field theory of localization, and what the role of the second parameter is.

In this paper we answer those questions by examining the crucial and largely unexplored role played by topological defects in the NL $\sigma$ M in the 2D symplectic class[23]. We show that localization is driven by the proliferation of pointlike  $Z_2$  vortices, and that the sign of the vortex fugacity distinguishes a TI from a trivial insulator. We find that average symmetries can place the system

on a line where the vortex fugacity vanishes, dictating delocalization. This analysis also provides new insight into the 2D symplectic metal-insulator transition. We find two distinct but equivalent fixed points describing transitions to insulator and TI states. By treating the number of replicas,  $N$  as a continuous variable, we show that for  $N = 1 - \epsilon$  the Anderson transition fixed points are perturbatively connected to the Kosterlitz-Thouless (KT) transition fixed point[24] for  $\epsilon \rightarrow 0$ . This allows us to compute the critical conductivity and correlation length exponent perturbatively in an  $\epsilon$  expansion.

Before describing the symplectic class, we briefly discuss a simpler version of delocalization via average symmetry in the unitary class. The surface of a 3D strong TI (STI) is delocalized[9, 25], but TR violating perturbations lead to localization. The localized state is in a sense “half” of a quantum Hall state, and has  $\sigma_{xy} = \pm e^2/2h$ . Importantly, the time reverse of this state, with  $\sigma_{xy} = \mp e^2/2h$ , is topologically distinct. If impurities have random local moments so TR symmetry is unbroken on average then the system is precisely at the transition between the two localized states. This can be modeled by an ensemble in which each member violates TR, but the whole ensemble is TR invariant. This is described by a NL $\sigma$ M in the unitary class, which in 2D allows a topological term[6] characterized by an angle  $\theta$  related to the Hall conductivity. Since TR, applied to the ensemble, takes  $\theta$  to  $-\theta$ , average TR symmetry constrains  $\theta$  to be 0 or  $\pi$ . The surface of a STI corresponds to  $\theta = \pi$ , so the surface is precisely at the critical point of the quantum Hall plateau transition[26]. If the average symmetry is broken by an applied magnetic field, then the system flows to a localized phase with  $\sigma_{xy} = \pm e^2/2h$ .

WTI and TCI surfaces also have discrete average sym-

metries. For a layered WTI it is translation by one layer. For the TCI studied in Ref.[22], it is a mirror symmetry. Breaking the symmetry gaps the surface, leading to localization. However, applying the symmetry to the gapped state leads to a topologically distinct localized state, so that there exists a 1D helical edge mode at the interface between the two localized states. If the symmetry is respected on average, then the system is at the boundary between the two localized states. It is clear that even for strong disorder, the system can not be localized at this point because a change in topological class can only occur when extended states are present at the Fermi energy.

To develop a field theory for this delocalization, we use the fermionic replica theory introduced by Efetov et al.[13]. Our analysis closely parallels that of Ryu, et al.[9]. We consider a system with average Hamiltonian  $\mathcal{H}_0$  and Gaussian correlated TR invariant disorder. Using the replica trick, the disorder averaged product of retarded and advanced Green's functions can be generated from the partition function  $Z = \int D[\bar{\psi}, \psi] e^{-S}$ , with

$$S = \int d^2r [\bar{\psi}_a ((\mathcal{H}_0 - E)\delta_{ab} + i\eta\Lambda_{ab})\psi_b - \frac{g}{2}(\bar{\psi}_a\psi_b)(\bar{\psi}_b\psi_a)] \quad (1)$$

Here  $a = 1, \dots, 2N$  is an index for  $N$  retarded and  $N$  advanced replicas, and  $\Lambda = 1_N \oplus (-1)_N$ , where  $1_N$  is a  $N \times N$  identity matrix.  $g$  is a coupling constant that characterizes the disorder strength, and  $\psi_a$  is a Grassman field that includes (suppressed) spin, position and possibly orbital indices.  $\bar{\psi}_a \equiv \psi_a^T i\sigma^y$ , where  $\sigma$  acts on the spin indices. TR requires  $\sigma^y \mathcal{H}_0 \sigma^y = \mathcal{H}_0^*$ , so  $i\sigma^y(H_0 - E)$  is a skew symmetric matrix. For  $\eta = 0$ , (1) is invariant under  $O(2N)$  rotations among the replicas, which is broken down to  $O(N) \times O(N)$  by  $\eta$ .

A theory of the Nambu Goldstone modes associated with this symmetry breaking is formulated by Hubbard Stratonovich decoupling the four fermion interaction, and performing a saddle point expansion about the broken symmetry state. After freezing the massive modes, the saddle point is characterized by a  $2N \times 2N$  matrix field  $Q = O^T \Lambda O$ , with  $O \in O(2N)$ . Distinct values of  $Q$  belong to the coset  $G/H = O(2N)/O(N) \times O(N)$  and satisfy  $Q = Q^T$ ,  $Q^2 = 1$ . A theory for the long wavelength fluctuations in  $Q_{ab}$  is obtained by integrating  $\psi_a$  in the background of a spatially varying  $Q_{ab}$ . This gives  $Z_{\text{eff}} = \int D[Q] e^{-S_{\text{eff}}[Q]}$  with

$$e^{-S_{\text{eff}}[Q]} = \int D[\bar{\psi}, \psi] e^{-\int d^2r [\bar{\psi}_a ((\mathcal{H}_0 - E)\delta_{ab} + i\Delta Q_{ab})\psi_b]} \quad (2)$$

Here  $\Delta$  is a parameter characterizing the bare scattering time that is determined self consistently at the saddle point. Expanding in gradients gives the NL $\sigma$ M,

$$S_{\text{eff}}^0[Q] = \frac{1}{32\pi t} \int d^2r \text{Tr}[(\nabla Q)^2], \quad (3)$$

where the coupling constant  $t$  characterizes the disorder

strength and is related at lowest order to the resistivity,  $\sigma = (2\pi t)^{-1} e^2/h$ . The renormalization of  $t$  at long wavelengths is described by the perturbative renormalization group (RG) equation[13, 14, 27–29]

$$dt/d\ell = \beta(t), \quad \beta(t) = 2(N-1)t^2 + \dots \quad (4)$$

In the replica limit,  $N \rightarrow 0$ , the weak coupling fixed point  $t = 0$  is stable, indicating the stability of the symplectic metal phase, characterized by weak antilocalization.

Eq. 3 is not the whole story because topologically non trivial configurations of  $Q$  can have important non-perturbative effects. There are two types of topological configurations associated with the nontrivial homotopy groups  $\pi_1(G/H) = \pi_2(G/H) = Z_2$ [10].  $\pi_2(G/H)$  allows a topological term that prevents localization on the surface of 3D TI[8, 9]. That term is absent in purely 2D systems as well as WTI or TCI surfaces. For our problem, the crucial topological objects are point-like defects similar to vortices that are allowed by the non trivial  $\pi_1(G/H)$ . These defects are necessary for localization, and their contribution to  $Z_{\text{eff}}$  encodes the distinction between a trivial insulator and TI.

The role of vortices can be understood by considering an inhomogeneous 2D system in which a TI in region  $S$  with boundary  $C$  is surrounded by a trivial insulator (Fig. 1a). Imagine integrating out  $\psi_a$  in (2) in the presence of a vortex configuration  $Q_{ab}(\mathbf{r})$ . Since the interior of  $S$  has a finite gap, the dominant contribution comes from the 1D helical edge states at the boundary  $C$ . On  $C$ ,  $Q_{ab}(\mathbf{r} \in C)$  is a non-singular and non-contractible configuration corresponding to the nontrivial element of  $\pi_1(G/H)$ . Repeating the analysis of Ryu *et al.*[9] for 1D helical states, we find a topological term in the 1D NL $\sigma$ M[10],

$$e^{-S_{\text{eff}}[Q]} \propto (-1)^{n(C)} \quad (5)$$

where  $n(C) = 0, 1$  is the  $Z_2$  homotopy class of  $Q$  on  $C$ . Importantly, since  $Q$  is defined in all space (except at the cores of vortices),  $n(C)$  is equal to the number of vortices inside the TI mod 2. This leads to a *bulk* characterization of the TI based on the 2D NL $\sigma$ M: *in the TI the fugacity  $v$  of  $Z_2$  vortices is negative*. In the trivial insulator the topological term is absent and  $v > 0$ , which is obvious for vanishing spin-orbit coupling since  $e^{-S_{\text{eff}}[Q]}$  is a perfect square due to spin degeneracy.

At the transition between the trivial and TI,  $v$  must pass through zero. This suggests  $v = 0$  at the WTI surface. To demonstrate this explicitly, we model a WTI as a layered 2D TI with helical edge modes  $H = v_x \sigma_x k_x$  stacked in the  $y$  direction with separation  $a$ . Coupling between layers gaps the surface, except at two Dirac points at  $(k_x, k_y) = (0, 0)$  and  $(0, \pi/a)$ . Indexing the Dirac points by  $\tau_z = \pm 1$ , the surface states are described by

$$H_0 = v_x \sigma_x k_x + v_y \sigma_y \tau_z k_y + m \sigma_y \tau_y \quad (6)$$

FIG. 1: (a) A 2D TI ( $m < 0$ ) in region  $S$  with boundary  $C$  is surrounded by trivial insulator ( $m > 0$ ). The sign of  $Z_{\text{eff}}$  depends on the number of vortices in  $S$ . (b) For  $m = 0$  the eigenvalues of  $\mathcal{H}^{\text{eff}}$  in (10) exhibit a linear zero crossing, which leads to a vanishing vortex fugacity.

The symmetry of the WTI under translation by one layer is described by  $\exp(ip_y a) = \tau_z$ . Dimerization of the layers breaks this translation symmetry, and generates a mass term  $m\sigma_y\tau_y$ [19]. This is the only mass that respects TR. The topologically distinct dimerization patterns are distinguished by  $\text{sgn}(m)$ . The sign reversal of the Dirac mass  $m$  also describes the low-energy theory of the 2D transition between a trivial and topological insulator[30].

Eq. 3 should include a sum over vortex configurations in  $Q$ . The vortex fugacity is determined by comparing (2) in the presence and absence of vortices. Consider the simplest vortex configuration involving a single retarded and advanced pair of replicas. This can be expressed in terms of a one parameter family of  $Q$ 's of the form

$$Q(\theta) = 1_{N-1} \oplus \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix} \oplus 1_{N-1}. \quad (7)$$

A  $Z_2$  vortex is then a configuration where  $\theta$  winds by an odd multiple of  $2\pi$ .

The Grassman integral in (2) defines a Pfaffian, so that the vortex fugacity may be written

$$v = \frac{\text{Pf}[i\sigma^y D(Q)]}{\text{Pf}[i\sigma^y D(Q_0)]}, \quad (8)$$

where  $Q$  is a vortex configuration, and  $Q_0 = \Lambda$ . In the space of the two nontrivial replicas we have

$$D(Q) = (\mathcal{H}_0 - E) + i\Delta(\mu^z \cos \theta + \mu^x \sin \theta). \quad (9)$$

Here  $\mu_z$  is a Pauli matrix in the space of the two nontrivial replicas. To evaluate the Pfaffian, we use a trick similar to that used by Ryu *et al.*[9], and compute  $(\text{Pf}[i\sigma^y D])^2 = \det[i\sigma^y D] = \det[\mu^y D]$ . This is useful because  $\mu^y D \equiv \mathcal{H}^{\text{eff}}$  is a Hermitian operator given by

$$\mathcal{H}^{\text{eff}} = \mu^y(\mathcal{H}_0 - E) + \Delta(\mu^x \cos \theta - \mu^z \sin \theta), \quad (10)$$

so the determinant is the product of its real eigenvalues. The TR symmetry of the original  $\mathcal{H}_0$  becomes a particle-hole symmetry,  $\{\mathcal{H}^{\text{eff}}, \Xi\} = 0$ , with  $\Xi = \mu^y\sigma^y K$ . Moreover, when  $m = 0$ ,  $\mathcal{H}^{\text{eff}}$  decouples into two independent Hamiltonians for  $\tau^z = \pm 1$ . Each is identical to a topological superconductor in class D, with  $\theta$  playing the role of the superconducting phase. There are two zero

modes indexed by  $\tau^z = \pm 1$  bound to the core of a  $Z_2$  vortex. For  $m \neq 0$ , the zero modes couple and split (Fig. 1b). Thus  $\det[\mu^y D]$  has a second order zero at  $m = 0$ , so  $\text{Pf}[i\sigma^y D]$  has a first order zero, which involves a sign change as a function of  $m$ . This shows that  $v = 0$  for  $m = 0$ , so isolated  $Z_2$  vortices are *forbidden* at the WTI surface. With multiple vortices the zero modes will split even for  $m = 0$ , leading to a nonzero Pfaffian. However, since the splitting vanishes exponentially in the separation, the vortices will be confined by a linear potential.

It is thus clear that the vortex fugacity  $v$  is a crucial variable in the NL $\sigma$ M. The TI and trivial insulator involve vortex proliferation and are distinguished by  $\text{sgn}(v)$ . For  $v = 0$ , qualitatively different behavior is expected reflecting the delocalization of the WTI or TCI surfaces. For  $v = 0$  the target space of the NL $\sigma$ M effectively lifts to its double cover,  $\tilde{G}/\tilde{H} = SO(2N)/SO(N) \times SO(N)$ , for which  $\pi_1(\tilde{G}/\tilde{H}) = 0$ . Since  $G/H$  and  $\tilde{G}/\tilde{H}$  have identical local structure, their perturbative  $\beta$  functions will be identical. It is useful to first consider this behavior as a function of the replica number,  $N$ .

For  $N > 1$ ,  $\beta(t) > 0$ , and the weak coupling fixed point is unstable, leading to a disordered phase even for  $v = 0$ . This phase is “less disordered” than the  $v \neq 0$  disordered phase, though. The confinement of  $Z_2$  vortices leads to a topological order similar to a  $Z_2$  spin liquid[31]. This can be seen by placing the system in a torus: there are four topologically disconnected sectors corresponding to the homotopy classes of  $Q \in G/H$  along the two large loops. When  $v$  is turned on in this disordered phase, the  $Z_2$  vortices immediately condense. The  $v = 0$  line thus describes a first order transition between the  $v > 0$  and  $v < 0$  phases.

The behavior for  $N \rightarrow 0$  is expected to be qualitatively different. In this case the weak coupling fixed point is stable and describes an ordered phase, which is present even for  $d \leq 2$ [32]. More importantly, the arguments for the absence of localization under strong disorder presented above prove that for  $v = 0$  the NLSM at strong coupling cannot be in a disordered phase. It is useful to consider the critical value  $N = 1$  that separates these behaviors. The theory for  $N = 1$  is simply the XY model, and  $Q$  is fully parameterized by  $\theta$  in (7). Eq. 3 becomes

$$S_{N=1} = \frac{1}{16\pi t} \int d^2 r (\nabla \theta)^2. \quad (11)$$

Since the target space,  $S^1$ , is flat,  $\beta(t) = 0$  to all orders. Vortices modify the behavior. For small  $t$ ,  $2\pi$  vortices in  $\theta$  are bound, and the system flows to a fixed line parameterized by  $t$ . For  $t > t^* = 1/16$  vortices unbind at a KT transition[24] to a disordered phase.

We now consider the behavior for  $N < 1$ , treating  $N$  as a continuous variable. Since  $Z_2$  vortices are present for all  $N$ , it is reasonable to examine their effects as a function on  $N$ . We find that the theory can be controlled for  $N = 1 - \epsilon$ , with  $\epsilon \ll 1$ . To lowest order in  $\epsilon$  and  $v$ ,

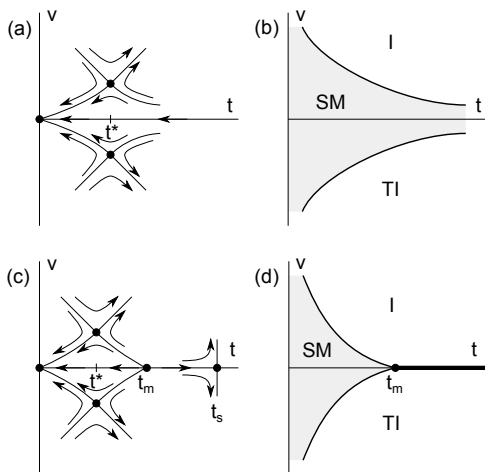

FIG. 2: (a,c) RG flow diagrams based on (12). The stable fixed point at  $(t, v) = (0, 0)$  is the symplectic metal (SM). The unstable fixed points at  $(t^*, \pm v^*)$  approach the KT transition for  $\epsilon = 1 - N \ll 1$  and for  $N \rightarrow 0$  are identified with the Anderson transition. (c) includes a third fixed point at  $(t_m, 0)$ , along with a fixed point at  $(t_s, 0)$  describing a direct transition between TI and I. (b) and (d) are phase diagrams corresponding to (a) and (c).

the KT flow equations are modified by the nonzero (but small)  $\beta(t) \equiv (N - 1)\tilde{\beta}(t)$ ,

$$\begin{aligned} dt/d\ell &= -\epsilon\tilde{\beta}(t) + v^2 \\ dv/d\ell &= (2 - (8t)^{-1})v. \end{aligned} \quad (12)$$

To this order, we are free to set the coefficient of  $v^2$  to one by rescaling  $v$ . The RG flows are shown in Fig. 2. There are two fixed points at

$$t^* = 1/16, \quad v^* = \pm[\epsilon\tilde{\beta}(t^*)]^{1/2} \quad (13)$$

For small  $\epsilon$ , these fixed points are within perturbative range of the KT fixed point. They describe a transition between the ordered and disordered phases of the  $O(2N)/O(N) \times O(N)$  NL $\sigma$ M for  $N < 1$ . For  $N \rightarrow 0$  we identify these fixed points with the Anderson transition between the symplectic metal and the localized trivial/topological insulator. Our theory implies that these two transitions have identical bulk critical behaviors, since the total number of  $Z_2$  vortices in a closed system is always even, so their total contribution to the partition function is always positive.

By expanding (12) about the fixed point, we can identify the critical conductivity and the correlation length exponent associated with the symplectic Anderson transition. To lowest order in  $\epsilon$  we find  $\sigma^* = (2\pi t^*)^{-1} e^2/h = (8/\pi)e^2/h$ , and  $\nu = 2t^*/(\epsilon\tilde{\beta}(t^*))^{1/2}$ . While  $\tilde{\beta}(t^*)$  is not known exactly,  $\beta(t)$  has been computed perturbatively up to order  $t^5$ [28]. The small value of  $t^*$  is well within the range of this perturbation theory. The second order term gives only 6% correction and the higher terms

are even smaller. Using the first term from (4) we find  $\nu = (2/\epsilon)^{1/2}$ . Extrapolating to  $\epsilon = 1$  gives

$$\sigma^* \sim 2.5e^2/h, \quad \nu \sim 1.4. \quad (14)$$

These values are rather different from numerical estimates in previous model studies, which give  $\sigma^* \sim 1.4e^2/h$  and  $\nu \sim 2.7$ [16, 33–35], though early work on the metal to TI transition found  $\nu = 1.6$ [15]. We suggest two possible origins of the discrepancy, depending on the behavior of the  $N = 0$  NL $\sigma$ M at strong coupling, which cannot be accessed in the present analysis. One possibility is that for  $N \rightarrow 0$ ,  $\beta(t) < 0$  for all  $t$  along the line  $v = 0$ . The corresponding RG flow and phase diagrams are shown in Fig.2a-b. In this case, the symplectic metal-insulator transition is governed by the fixed point  $(t^*, v^*)$ . The discrepancy in exponents is then most likely due to the slow convergence of the  $\epsilon$  expansion similar to the  $d = 2 + \epsilon$  expansion for the 3D Anderson transition.

A second possibility is that for  $N \rightarrow 0$ ,  $\beta(t)$  changes sign at a critical point  $t_m$  on the line  $v = 0$ , as hypothesized in Ref. 8 in a different context. In fact,  $t_m$  is present for  $N = 1 - \epsilon$ . For  $N = 1$ , double vortices are allowed, and will in general have non zero fugacity. The theory with both single and double vortices can be analyzed using a dual sine-gordon theory,

$$S = \int d^2r \frac{t}{\pi} (\nabla\varphi)^2 + v \cos\varphi + v_2 \cos 2\varphi, \quad (15)$$

where  $v_2$  is the fugacity for double vortices. When  $v = 0$ ,  $v_2$  becomes relevant at  $t_m = 1/4$ . When  $v_2$  flows to strong coupling,  $v = 0$  describes a first order transition similar to the case when  $N > 1$ . It is unlikely that this first order transition persists to  $N = 0$ , which is a theory of disordered non-interacting electrons. Instead, the most likely scenario is a continuous direct transition between trivial insulator and TI controlled by a strong coupling fixed point  $t_s$ , as indicated in Fig. 2c-d. In this scenario, while the ultimate critical behavior is controlled by the identical fixed points  $(t^*, \pm v^*)$ , finite size crossover effects associated with  $t_m, t_s$  could obscure the behavior.

- [29] Our normalization of  $t$  in (3) and (4) is chosen to be consistent with  $\beta(t)$  in Refs. 14, 27, 28. In Ref. 13,  $t$  differs by a factor of  $32\pi$ , and is rescaled by  $2\pi$  in  $\beta(t)$ .  $N$  differs by a factor of 2. The relation between  $t$  and  $\sigma$  is fixed by comparing (4) with the weak antilocalization correction to  $\sigma$ .
