(Dated: December 3, 2015)

We report the first application of critical cluster techniques to the Mott metal-insulator transition in vanadium dioxide. We show that the geometric universal properties of the metallic and insulating puddles observed by scanning near-field infrared microscopy are consistent with the system passing near criticality of the random field Ising model as temperature is varied. The resulting large barriers to equilibrium may be the source of the unusually robust hysteresis phenomena associated with the metal-insulator transition in this system.

The Mott metal-insulator transition in VO$_2$ has the potential to produce disruptive technologies, such as memristors, memory capacitors, ultrafast switches, and possibly even neuromorphic circuits [1]. Yet despite decades of research into VO$_2$, the nature of the phase transition, and in particular the broad hysteretic behavior accompanying it, is not yet understood. In V$_2$O$_3$, there is a first order phase transition whose critical endpoint was argued to be in the universality class of the clean three-dimensional (3D) Ising model [2–4]. In VO$_2$, the resistance avalanches observed in Ref. 5 were interpreted in terms of the universality class of uncorrelated percolation [5]. Here, we argue that the first order metal-insulator transition in VO$_2$ is also near a critical endpoint which can be reached by tuning disorder. Using quantitative cluster techniques, we argue that the critical endpoint is in the universality class of the random field Ising model, which is well-known for nonequilibrium effects such as broad hysteresis.

As shown in Fig. 1, scanning near-field infrared microscopy (SNIM) on VO$_2$ [6] reveals that the transition from the low temperature insulating phase to the high temperature metallic phase is accompanied by the complex pattern formation expected in a disordered correlated electronic system, in which spatial fluctuations in disorder nucleate different phases [7]. Using recently developed cluster techniques [8], we show below that the cluster statistics are power law over 2.5 decades, consistent with proximity to a critical endpoint of the first order phase transition. In fact it has recently been shown that the hysteretic behavior in VO$_2$ can be tuned through a critical endpoint via doping [9, 10]. Fig. 2(a) shows the coexistence region, inferred by taking the maximum slope of resistivity vs. temperature curves as a function of Nb doping from Fig. 3(b) of Ref. 9.

We analyze the SNIM images in Fig. 1 under the assumption of proximity to this critical endpoint. In the original SNIM data images [6], we assign Ising variable $\sigma = 1$ (metallic) or $-1$ (insulating) to each coarse-grained region [2–4, 12, 13]. Our results are robust against changes of as much as 15% in the threshold amplitude $a_{th}$ used to identify metallic regions (those with scattering amplitude $a > a_{th}$) and insulating regions (with $a \leq a_{th}$), and in the main text we show results with the representative value of $a_{th} = 2.5$. (See SI.) We furthermore incorporate disorder into the model:

$$H = -\sum_{\langle ij \rangle} (J + \delta J_{ij})\sigma_i\sigma_j - \sum_{\langle ij \rangle} (J + \delta J_{ij})\sigma_i\sigma_j - \sum_i (h + h_i)\sigma_i ,$$

where the sum runs over the coarse-grained regions (sites) consisting of a cubic lattice, chosen with spacing at least as small as the resolution of the images to be studied.

![Image](image_url)
The tendency for neighboring regions to be of like character is modeled as a nearest neighbor ferromagnetic interaction \( J > 0 \). Because the data considered is that of a thin film, the sum over Ising variables in the plane of the film (denoted by \( \parallel \) ) extends to infinity, but the sum over Ising variables perpendicular to the film surface (denoted by \( \perp \) ) is finite, confined by the film thickness \( L_z \).

At the order parameter level, there are two broad classes of disorder: local energy density disorder (which we incorporate as random bond disorder), and random field disorder [14]. In Eqn. 1, random bond disorder is included through the term \( \delta J_{ij} \), and \( h_i \) represents random field disorder, which is chosen from a gaussian probability distribution centered about zero, with variance \( R \). \( R \) is often called the disorder parameter or just disorder. Because the field \( h \) represents a generalized external field which couples with the local Ising variables, tuning temperature in experiment also sweeps the generalized field \( h \) in the model, as schematically illustrated in Fig. 2(c).

Using the mapping to Ising variables (Fig. 1), we track the geometric clusters, defined as connected sets of nearest neighbor sites (pixels) with the same color. We then use the statistics of the sizes and shapes of these clusters to identify the cause of the pattern formation. In comparing the spatial complexity revealed in the SNIM data to theory, there are 7 fixed points of Eqn. 1 to consider [8]. In the two-dimensional case, these consist of the clean Ising model (C-2D), uncorrelated percolation (P-2D), and the random field Ising model (RF-2D). Note that random bond disorder is irrelevant in the renormalization group sense in 2D, and the phase transition is therefore governed by clean Ising model exponents (C-2D). In the three-dimensional case, the possible fixed points are the clean Ising model (C-3D), uncorrelated percolation (P-3D), the random bond Ising model (RB-3D), and the random field Ising model (RF-3D).

From the SNIM images, we extract three critical exponents from the self-similarity of the geometric clusters near certain critical points: The Fisher exponent \( \tau \) characterizes the cluster-size distribution \( D(s) \propto s^{-\tau} \). The volume fractal dimension \( d_v \) and the hull fractal dimension \( d_h \) characterize the fractal nature of cluster sizes \( s \) and hulls \( h \). For the cluster sizes, \( s \propto R_v^{d_v} \), where \( R_v \) is the radius of gyration of the cluster [15]. For the cluster surfaces, \( h \propto R_h^{d_h} \), where \( R_h \) refers to the radius of gyration of all the sites enclosed by the hull, including any subclusters inside. To reduce noise due to the finite field of view (FOV), we apply logarithmic binning [16] throughout this Letter. The values of critical exponents are obtained by taking the discrete logarithmic derivative (DLD) [17]. We restrict our analysis to internal clusters, i.e., clusters which do not intersect the boundary of the FOV, in order to mitigate finite FOV effects which skew the estimated values of the extracted exponents [18, 19].

The main panels in Fig. 3 show explicitly the power law fits of internal clusters from the VO\(_2\) SNIM image datasets with threshold scattering amplitude \( a_{th} = 2.5 \) for (a) \( D(s) \propto s^{-\tau} \), (b) \( R_v \propto s^{1/d_v} \), and (c) \( R_h \propto h^{1/d_h} \), at three intermediate temperatures \( T = 342.6K \), \( T = 342.8K \), and \( T = 343K \). The insets show the extracted \( \tau \), \( 1/d_v \), and \( 1/d_h \) (with error bars) as a function of \( a_{th} \) at \( T=342.8K \).
Only two candidate fixed points remain inconsistent the value of $d$, and cross sections of the clusters embedded in 3D, with the first bin (which contains slope as the full system [19]. For the fractal dimensions, effects, since within a cutoff in the decades of scalar, the effective values of $d_s$ and $d_h$ corresponding to taking 2D cross sections of the clusters embedded in 3D, i.e. $d_v = 2d_h/3$ and $d_h^* = d_h/2$ [8]. These effective values are represented by the open circles.

The other candidate dimensional crossover is from RF-2D to RF-3D, the value of $d_v$ is much closer to C-2D than to P-3D, consistent with the geometric clusters being near their 2D limit, whereas the value of $d_h$ is much closer to P-3D than to C-2D, indicating that the geometric clusters are near their 3D limit. This inconsistency strongly argues against the P-3D to C-2D dimensional crossover as the origin of the power law behavior.

The other candidate dimensional crossover is from RF-3D to RF-2D. The exponent comparisons show no inconsistency with this explanation, since within error bars $\tau$ and $d_v$ match the RF-2D to RF-3D crossover regime, and $d_h$ is also consistent with this dimensional crossover. Therefore, the random field Ising universality class best describes the critical behavior of the Mott transition in the VO$_2$ thin film, revealing the key role played by disorder effects in these systems. Observations at longer length scales can be used to test this hypothesis: if our identification is correct, then the values of all exponents should drift toward RF-2D with larger fields of view in a film geometry such as the present one.

In order to further test whether the spatial complexity is driven by random field effects, we also analyze the avalanches which, in the context of the VO$_2$ experiment, are defined as the difference between Ising maps between two neighboring temperatures. Figure 5 shows the power law fits of the internal avalanches with threshold $a_{th} = 2.5$ for the data-extracted $\tau^*$, $d_v^*$, and $d_h^*$, using the same techniques as for the clusters in Fig. 3. The prime symbol is used to denote that these exponents are for avalanches. Similar to their cluster counterparts, the cut-off for internal avalanche scaling for $\tau^*$ is about 1.5 to 2 decades of scaling, and $d_v^*$ and $d_h^*$ show multiple decades

![FIG. 4. Exponent comparison charts. (a) Critical exponent $\tau$. (b) Critical exponents $d_v$ (blue) and $d_h$ (green). The horizontal lines are our extracted exponents from the SNIM images, with the shaded regions being their error bars. The circles represent theoretical values [8, 20] for the fixed points of Eqn. 1. When comparing with 3D models, we have to use the effective values of $d_v$ and $d_h$ corresponding to taking 2D cross sections of the clusters embedded in 3D, i.e. $d_v = 2d_h/3$ and $d_h^* = d_h/2$ [8]. These effective values are represented by the open circles.](image)
of power law scaling behavior. For different intervals, the extracted critical avalanche exponents are consistent with each other within error bars. This data-extracted robust universal power law scaling of avalanches provides further evidence that the random field universality is underlying the complex pattern formation at the Mott transition in the VO$_2$ thin film, since non-trivial scaling behavior of avalanches is characteristic of random field physics.

Since the avalanches are taken from the finite interval between scanned images, the data-extracted $\tau^*$ in our context characterizes the scaling of the field integrated avalanche size distribution $D_{int}(s)$ near criticality. The corresponding exponent is reported to be $2.03 \pm 0.03$ for RF-3D [18, 27, 28] and $1.3 \pm 0.1$ for RF-2D [29], and the corresponding data-extracted one from Fig. 5(a) lies in between, consistent with the conclusion of a dimensional crossover from RF-3D to RF-2D. With $d'_c$ and $d'_h$ only reported for RF-3D [28], our data-extracted fractal dimensions (Fig. 5(b) and 5(c)) could not be directly compared with the theoretical ones for the RF-3D to RF-2D crossover. However, within error bars, $d'_c$ and $d'_h$ extracted from avalanches have the same values as $d_c$ and $d_h$ extracted from clusters (Fig. 3(b) and 3(c)). This is consistent with Ref. [28], which shows that clusters and avalanches have the same exponents in the random field Ising model (RFIM).

The dominance of random field disorder is quite reasonable in a real physical system, arising from defects and impurities in the crystal structure; randomness in grain size, orientation, and boundary structure; and imperfections in the substrate. In the case of the sample under consideration, a likely source of random field effects is grain boundaries, as supported by our prior work showing that metallicity nucleates first near grain boundaries [30]. (See SI for a discussion of microscopic sources of disorder.) Several other characteristics of the data serve to corroborate the random field hypothesis. For example, as the Mott transition proceeds, metallic puddle formation occurs via nucleation and not just by front propagation [31], as shown in Fig. 1. In addition, as temperature increases through the transition (analogous here to sweeping the generalized field $h$ of Eqn. 1), domains change from $\sigma = -1$ to $\sigma = +1$, but never revert. This no-passing rule is consistent with the random field universality class [28, 32, 33], indicating that the effects of quenched disorder dominate over thermal fluctuations. The dominance of quenched disorder over thermal effects is further corroborated by the reproducibility of the SNIM images, in that repeated near-field scans in the insulator-to-metal transition regime over the same sample area and at a fixed temperature show nearly identical patterns of metallic puddles in the insulating host [6, 34].

Finally, perhaps the most tell-tale sign of random field behavior in the data is the large width of the hysteresis in temperature, about 7.5K for temperature sweeps taking several minutes in a thin film [34, 35]. The extreme critical slowing down of the random field case means that barriers to equilibration grow much more severely as criticality is approached than the usual “critical slowing down” would predict. Hysteresis typically becomes long-lived near the critical endpoint of a first order phase transition, with the relaxation time $t_{rel}$ diverging as a power law near the critical endpoint [36], $t_{rel} \propto |g - g_c|^{-\nu z}$, where $g$ represents the relevant variable, whether temperature $T$ or disorder strength $R$. $\xi$ is the correlation length, $\nu$ is the exponent of the correlation length, and $z$ is the dynamical exponent. Rather than a mere power law, barriers to equilibration grow exponentially near the RFIM critical endpoint [37], $t_{rel}^{RFIM} \propto \exp[\xi^g] \propto \exp[1/(g-g_c)^{\nu \theta}]$, where $\theta$ is the ”violation of hyperscaling” exponent. These exponentially large barriers to equilibration are consistent with the large width of hysteresis loops evident in this Mott metal-insulator transition. In addition, the large critical region typically associated with RFIM physics [18] is consistent with the wide range of parameters over which the broad hysteresis is observed.

In conclusion, by applying newly developed cluster techniques to SNIM data on VO$_2$, we have shown using six different critical exponents that the critical end point of the Mott transition is in the universality class of the random field Ising model. This finding reveals a delicate interplay between interaction and disorder in these systems. The random field Ising universality class has also recently been shown to account for the spatial structure of the locally oriented domains observed via scanning tunneling microscopy on cuprate superconduc-
tors [8, 38]. This further emphasizes the important role played by disorder in strongly correlated electron systems, and indicates that there may be universality to the spatial complexity [7, 39] observed in a wide variety of strongly correlated electron systems. The cluster techniques employed here can readily be applied to scanned images in the context of other materials and microscopy techniques for the study of universal behaviors underlying the spatial complexity.

[11] Note that while there is some spectroscopic difference between the infrared characteristics of the metallic puddles in the coexistence regime and the high temperature rutile metal [6], the coexistence regime is 2-phase and so it can be captured within an Ising description.
