We present an angle-resolved photoemission study of the electronic structure of the threedimensional pyrochlore iridate $Nd_2Ir_2O_7$ through its magnetic metal-insulator transition. Our data reveal that metallic $Nd_2Ir_2O_7$ has a quadratic band, touching the Fermi level at the Γ point, similarly to that of $Pr_2Ir_2O_7$. The Fermi node state is, therefore, a common feature of the metallic phase of the pyrochlore iridates. Upon cooling below the transition temperature, this compound exhibits a gap opening with an energy shift of quasiparticle peaks like a band gap insulator. The quasiparticle peaks are strongly suppressed, however, with further decrease of temperature, and eventually vanish at the lowest temperature, leaving a non-dispersive flat band lacking long-lived electrons. We thereby identify a remarkable crossover from Slater to Mott insulators with decreasing temperature. These observations explain the puzzling absence of Weyl points in this material, despite its proximity to the zero temperature metal-insulator transition.

The 5*d* iridium oxides (iridates), having comparable scales for their kinetic energy, coulomb interaction and spin-orbit coupling, provide an excellent platform to study new types of strongly correlated phenomena [1– 11]. Amongst them, the pyrochlore iridates ($Ln_2Ir_2O_7$, where Ln is a lanthanide), endowed with frustrated geometry and cubic symmetry, have a particularly fascinating phase diagram. $Pr_2Ir_2O_7$, with the largest Ln-ion, is a metallic spin-liquid [12–14] and exhibits an anomalous Hall effect [15, 16]. For Ln-ions with smaller ionic radius, an antiferromagnetically ordered insulating phase appears at low temperature.

Theoretically, topological band structures have been ascribed to the $Ln_2Ir_2O_7$ series [4, 7, 17–19]. The metallic phase is predicted to exhibit quadratically dispersing conduction and valence bands touching at the Γ point close to the Fermi level (E_F) [20, 21]. This structure has been recently identified by angle-resolved photoemission spectroscopy (ARPES) in $Pr_2Ir_2O_7$ [22]. Theory predicts that such a quadratic Fermi node state may be converted into various topological states such as a topological insulator or a Weyl semimetal by appropriate symmetry breaking [4, 7, 17–19].

Antiferromagnetism in these materials is of Ising type, consisting of an "All-In-All-Out" (AIAO) configuration of Ir moments on alternating tetrahedra [23–26]. This can be considered an "octupolar" spin order which breaks time-reversal but preserves cubic symmetry, and does not enlarge the unit cell [27]. The Ising nature implies two types of domains, which have recently been shown, in agreement with theoretical predictions [28], to be separated by metallic domain walls [29, 30], which have been imaged by microwave impedance microscopy in the magnetic state of $Nd_2Ir_2O_7$ [26]. Early density functional studies predicted the magnetic state to be a Weyl semimetal [7], and general arguments imply that if a quasiparticle picture applies at low energy in the antiferromagnetic phase, and the magnetic ordering is weak, it *must* exhibit Weyl points and cannot have a true gap. Nevertheless, optical [31] and transport [29] measurements indicate a gapped insulating ground state for $Nd_2Ir_2O_7$, despite its low antiferromagnetic/Metal-Insulator (MI) transition temperature $T_{\rm MI} \approx 30 {\rm K}$ and proximity to metallic $Pr_2Ir_2O_7$. This begs the question of whether the weakness of the order, the quasiparticle assumption, or both, break down in this system. More generally, we seek to understand the influence of the MI transition on the conduction electrons.

In this letter, we use ARPES to investigate the evolution of the electronic structure through the MI transition in Nd₂Ir₂O₇, which is the most suitable member of the series for such study because its low $T_{\rm MI}$ minimizes thermal broadening. Although the layered iridates have been extensively studied by photoemission [2, 32–38], ours is the first study across a MI transition in any iridate, since the latter occurs only in the pyrochlores. Using highquality single crystals, we are able to directly measure both the single particle excitations of the metallic and insulating phases. Our data indicate that Nd₂Ir₂O₇ displays a dramatic Slater to Mott crossover with reducing temperature. This implies that Weyl fermions, if they exist, may do so only in a narrow region of temperature slightly below $T_{\rm MI}$, in which the order is indeed weak and quasiparticles can survive.

Single crystals of $Nd_2Ir_2O_7$ with $\sim 1 \text{ mm}^3$ in size were grown with a flux method. The surface measured by ARPES is the (111) plane. To get a clean surface, a typical cleavage method was used: a top-post glued on the crystal surface is hit *in-situ* to break the crystal. Flat, shiny portions exposed on the cleaved surface are tiny, but still large enough to be illuminated by the synchrotron beam ($\sim 100 \mu m$ in spot size). The ARPES experiments were performed at BL7U of UVSOR facility with a MBS A-1 analyzer $(h\nu = 8 \sim 18 \text{ eV})$ [39], BL28A of Photon Factory in KEK with a Scienta SES2002 analyzer ($h\nu = 39 \sim 60 \text{ eV}$), and 1^3 beamline in BESSY-II at Helmholtz-Zentrum Berlin with a Scienta R4000 analyzer ($h\nu = 50 \sim 60 \text{ eV}$). The overall energy resolution in ARPES was set to ~ 15 meV, and the lowest achievable temperature was 1K.

As previously reported, the transition temperature $T_{\rm MI}$ in $Ln_2 {\rm Ir}_2 {\rm O}_7$ [40] is controlled by the Ln-ion size [41], the pressure [41, 42], and the off-stoichiometry [43]. We have selected three pieces of Nd₂Ir₂O₇ crystals with different transition temperatures to investigate the variation of the MI transition with small changes in stoichiometry [29, 43, 44]. We identified, with an electron-probe microanalysis (EPMA), a slight deviation from stoichiometry in the Ir/Nd ratio of approximately 1% and 2% for the single crystals with zero-field $T_{\rm MI}$ of ~25K and ~20K, respectively. The off-stoichiometry of the crystals with the maximum $T_{\rm MI}$ of ~35K is below the threshold of detecting in EPMA, i.e. no larger than that in the $T_{\rm MI} \sim 25$ K samples.

Figure 1 shows the resistivity, $\rho(T)$, of the crystals we used for ARPES; note that we retrieved the crystal-piece after the ARPES experiment, and measured the resistivity of exactly the same piece to properly compare the ARPES and resistivity results. The temperature derivative of $\rho(T)$, $d\rho(T)/dT$, (inset panel) enables us to estimate the value of $T_{\rm MI}$ from the onset of its reduction. As marked by arrows, different transition temperatures $T_{\rm MI}$ of ~19K, ~25K, and ~36K were estimated for the three samples, which are thus labeled as MI19K, MI25K, and MI36K for the rest of the paper.

In Fig. 2, we examine the band structure in the metallic phase. Figure 2(c1) plots the typical ARPES spectra (energy distribution curves: EDCs) obtained at $(k_x, k_y)=(0,0)$ with low-energy photons (9.0eV $\leq h\nu \leq$ 11.5eV) corresponding to k_z (or $k_{(111)}$) values in the 1st Brillouin zone. Small but sharp quasiparticle peaks are observed for all of the photon energies as marked by arrows in Fig. 2(c1). We find that the quasiparticle peak approaches $E_{\rm F}$ with increasing photon energi

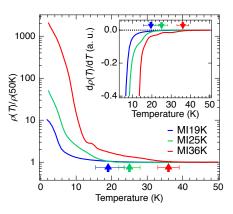

FIG. 1: (color online) Temperature dependence of the resistivity, $\rho(T)$, for Nd₂Ir₂O₇ crystals (MI19K, MI25K, and MI36K) we used for ARPES measurements. It is normalized to the intensity at T=50K. Inset panel plots the temperature derivative of the resistivity, $d\rho(T)/dT$. The transition temperature $(T_{\rm MI})$ estimated is marked by an arrow.

gies and moves away again after getting closest to it at $h\nu$ =10.5eV. In Fig. 2(c2), the EDCs are symmetrized about $E_{\rm F}$ to remove the effect of Fermi cut-off [22, 45]. We found that the gapped spectra with two peaks merge to one peak at 10.5eV, thus the band touching occurs in Nd₂Ir₂O₇ at the same photon energy as in Pr₂Ir₂O₇ [22]. To validate this further, we also used higher photon energies reaching the 3rd Brillouin zone (green circles in Fig. 2(a)), and reproduced the Fermi node again at Γ ($h\nu$ =53eV) as shown in Figs. 2(d1) and 2(d2) [45].

While ARPES is a technique to observe the occupied band structure, one can visualize the unoccupied states slightly above $E_{\rm F}$ by raising the sample temperature. Figure 2(b) demonstrate such an ARPES image along a k_x cut across Γ . Here the intensities are divided by the Fermi function at the measured temperature ($T=75{\rm K}$) to properly reveal the spectra above $E_{\rm F}$. The spectrum becomes broad due to the short lifetime characteristic of strongly correlated systems at high temperatures, so it is not possible to detect the quasiparticle peaks in the unoccupied side. Nonetheless, significant intensities, indicative of the theoretically predicted conduction-band, are visible (a black arrow in Fig.2(b)).

Intriguingly the band width of $Nd_2Ir_2O_7$ is found to be extremely narrow, of order ~40 meV on the occupied side, which is much less than expectated from DFT calculations. While a band narrowing is also reported for the other iridates such as Na_2IrO_3 [32], Sr_2IrO_4 [2], $Sr_3Ir_2O_7$ [33] and $SrIrO_3$ [34], it seems to be comparable or even more significant in the pyrochlore iridates, consistent with DMFT calculations [46]. Furthermore, we detect a peak-dip-hump structure in the spectra, as is often observed in strongly correlated systems. These results are consistent with those of $Pr_2Ir_2O_7$ [22]. The observations in both materials are consistent with a pic-

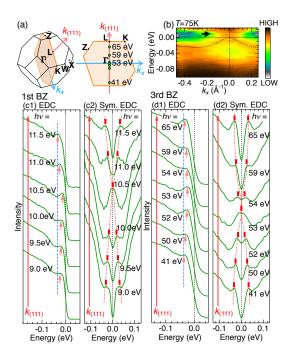

FIG. 2: (color online) (a) Brillouin zone for Nd₂Ir₂O₇. (b) Band dispersion map crossing Γ , divided by the Fermi function at the measured temperature (T=75K). The arrow indicates the intensities implying an expected conduction-band. EDCs (T=15K) at (k_x, k_y)=(0,0) measured with low-energy photons (c1) and high-energy photons (d1), corresponding to $k_{(111)}$ s in the 1st and 3rd Brillouin zone, respectively. (c2,d2) The same data as in (c1) and (d1), respectively, but symmetrized about $E_{\rm F}$. Arrows and bars mark peaks in the spectra.

ture of the metallic state as a highly renormalized Fermi liquid [54].

We now turn to the MI transition. In Fig. 3, we examine the temperature evolution of band dispersion through $T_{\rm MI}$, measured along a momentum cut across Γ (a light blue arrow in the inset of Fig. 3(c)). Figures 3(a1) and 3(a2) plot the dispersion maps for MI36K symmetrized about $E_{\rm F}$ and the 2nd derivative of those [45]. Notably the spectra above and at $T_{\rm MI}$ ${\sim}36{\rm K}$ are virtually identical, showing that there is no significant precursor of the MI transition. As temperature is dropped below $T_{\rm MI}$, a gap opens at the Fermi node. This variation is also seen in the ARPES mapping at $E_{\rm F}$ along a $k_x - k_y$ sheet (red plane in the inset of Fig. 3(c)); the strong intensity at Γ coming from the Fermi node [Fig. 3(d1), T=50K] vanishes below $T_{\rm MI}$ [Fig. 3(d2), T=11K]. The band dispersion, determined from the peak/shoulder of the EDC [Fig. 3(c)] also reflects the continuous opening of a gap below $T_{\rm MI}$. These observations are consistent with a mean-field quasiparticle dispersion, in which the gap is directly controlled by the antiferromagnetic order parameter.

However, the EDCs themselves reflect strong correlations. In Figs. 3(b1) and 3(b2), the spectra for T = 47K

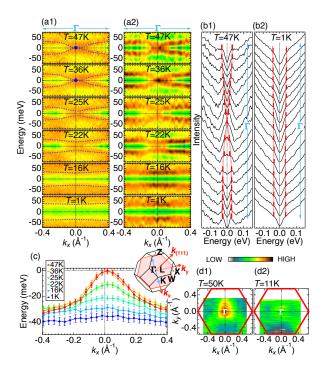

FIG. 3: (color online) (a1) Band dispersion map across Γ ($h\nu$ =53eV; a light blue arrow in the inset of (c)) measured at various temperatures for MI36K. The images are symmetrized about $E_{\rm F}$. Blue dashed curves indicate the obtained band dispersions. (a2) Second derivative plots for EDCs in (a1). (b1,b2) Spectra extracted from (a1) for the metallic phase (T=47K) and the insulating phase (T=1K), respectively. (c) Temperature dependence of the band dispersion determined from the spectral peaks or shoulders (red bars in (b1) and (b2)). (d1,d2) Spectral intensities at $E_{\rm F}$ along a momentum sheet crossing Γ (red region in the insulating phase (T =11K), respectively.

and 1K corresponding to the images in Fig. 3(a1) are plotted. The electronic structure in the metallic phase [Fig. 3(b1)] consists of well-defined quasiparticle peaks (red bars). In contrast, the insulating phase [Fig. 3(b2)] shows a non-dispersive flat band, and only the broad spectra lacking long-lived electrons are detected, pointing to correlation-induced Mott localization.

We investigate this further through the detailed variation of spectral-shape at Γ . Figure 4(a1-c1) show the symmetrized EDCs from above to below $T_{\rm MI}$ for the three samples (MI19K, MI25K, and MI36K); the gap is reflected in two split peaks (black arrows) below $T_{\rm MI}$. Please note that the tracing of peak positions slightly underestimates the "real" onset temperature of gap opening, especially in 3D materials with broadened spectra due to the imperfect sample surface and k_z broadening of ARPES. Nevertheless, the persistance of quasiparticle peaks below but near $T_{\rm MI}$ and their shift with temperature is in accord with a mean-field theory, and denote this as a "Slater picture" [47], though in Nd₂Ir₂O₇ there is no

(d1) The same data as in (c1), plotted without symmetrization. (a2-d2) The same data as in (a1-c1), but without an offset. (e) Temperature dependence of spectral wight loss near $E_{\rm F}$ ($W_{\rm loss}$), which is determined to be a negative area in the difference spectra as demonstrated in the inset. (f) Temperature dependence of the magnitude of energy gap estimated from the spectral peak positions marked in (a1-c1) by arrows.

unit cell enlargement, as envisioned in the original work of Slater [47], and observed in NaOsO₃ [48]. Enlargement is not necessary in Nd₂Ir₂O₇, since the unit cell already contains four Ir atoms in the metallic state. Our use of the term "Slater" reflects the more fundamental idea that the insulating behavior arises in a mean-fieldlike way from an exchange field in magnetic order, and follows other usage in the literature [49]. This physics is fully consistent with the observation of coherent muon spin precession, a signature of a long-range magnetic order, just below $T_{\rm MI}$ [24], and the recent discovery of an insulator to metal transition driven by external magnetic field in Nd₂Ir₂O₇ [29, 44], revealing that the destruction of AIAO magnetic order restores the metallic transport. The gap behavior we observe here is distinctly different from that in the planar iridate Na₂IrO₃, which remains unchanged across the magnetic transition temperature, and is thus categorized as a Mott-type insulator [32].

However, the data shows that the quasiparticle peak is significantly suppressed as temperature is further decreased, and it totally disappears at the lowest temperature, leaving only a broad spectrum. The abnormal variation of the quasiparticle peak is also visible in the raw EDCs [Fig. 4(d1)]. While a tiny peak survives in MI19K [see Fig. 4(a1)] even at T = 1K, it is attributable to small carrier doping in the insulating ground state due to the off-stoichiometry in the crystal [50]. This is compatible with the previous reports that the electronic state becomes less insulating with an increased off-stoichiometry [43, 51], eventually turning metallic down to the lowest temperature [52].

The peak suppression is examined in Fig. 4(a2-d2)in more detail, where the spectra of Fig. 4(a1-d1) normalized to the intensities around -0.3eV are overlapped with each other. The spectral weight at $E_{\rm F}$ is gradually depleted on cooling down to the lowest temperature. This feature is more clearly demonstrated in Fig. 4(e)by plotting a spectral loss near $E_{\rm F}$ ($W_{\rm loss}$, see the inset of Fig. 4(e)) associated with the gap formation. The pseudogap-like spectral loss quantifies the crossover from the Slater-like mean field behavior near $T_{\rm MI}$ to the Mott regime at the lowest temperature. The fact that the gap [Fig. 4(f)] reaches $\sim 30-40$ meV at low temperature (comparable to the optical results [31]), thus is as large as the measured bandwidth, indicates the strong coupling limit, and may be responsible for this crossover. We speculate that the enhancement of exchange field due to Nd ordering at below $\sim 15 \text{K}$ [53] may trigger the increased electron localization observed in ARPES.

Theory predicts that the Weyl points may migrate from the Γ point to the zone boundary and annihilate when the order parameter becomes too large [6, 18, 21], which may explain their absence in low temperature $Nd_2Ir_2O_7$. One might therefore contemplate their reappearance at intermediate temperatures just below $T_{\rm MI}$, where the gap is smaller and quasiparticles are still well-defined. However, no indication of Weyl points at intermediate temperatures was found in the present ARPES measurements. Apart from the difficulty of locating incommensurate temperature-dependent features in ARPES, the progressive destruction of quasiparticles we observed may be another reason for this. We leave a dedicated search for Weyl points just below $T_{\rm MI}$, perhaps using spin-resolved ARPES, for future work.

In conclusion, we carried out the first ARPES investigation of the MI transition of a three dimensional iridate. We observe a quadratic Fermi node in the metallic state of Nd₂Ir₂O₇ very similar to that of Pr₂Ir₂O₇. Upon lowering temperature below $T_{\rm MI} \sim 30$ K, we found a drastic variation in the spectral shape, with a gradual opening of a gap and accompanying suppression of the quasiparticle peak. At the lowest achievable temperature of 1K, quasiparticles are completely suppressed and a dispersionless spectral edge is observed. The results indicate a crossover from a Slater-like mean-field effective band insulator just below $T_{\rm MI}$ to a Mott-like insulator with localized electrons at the lowest temperature.

We thank H. Shinaoka and E.-G. Moon for fruitful discussions and constructive comments, and D. Evtushinsky and E. Rienks for technical supports at 1^3 beamline in BESSY-II.
