(Dated: October 28, 2016)

We report constraints on the sources of ultra-high-energy cosmic rays (UHECRs) above 10^9 GeV, based on an analysis of seven years of IceCube data. This analysis efficiently selects very high energy neutrino-induced events which have deposited energies from 5×10^5 GeV to above 10^{11} GeV. Two neutrino-induced events with an estimated deposited energy of $(2.6 \pm 0.3) \times 10^6$ GeV, the highest neutrino energy observed so far, and $(7.7 \pm 2.0) \times 10^5$ GeV were detected. The atmospheric background-only hypothesis of detecting these events is rejected at 3.6σ . The hypothesis that the observed events are of cosmogenic origin is also rejected at $>99\%$ CL because of the limited deposited energy and the non-observation of events at higher energy, while their observation is consistent with an astrophysical origin. Our limits on cosmogenic neutrino fluxes disfavor the UHECR sources

having cosmological evolution stronger than the star formation rate, e.g., active galactic nuclei and γ -ray bursts, assuming proton-dominated UHECRs. Constraints on UHECR sources including mixed and heavy UHECR compositions are obtained for models of neutrino production within UHECR sources. Our limit disfavors a significant part of parameter space for active galactic nuclei and new-born pulsar models. These limits on the ultra-high-energy neutrino flux models are the most stringent to date.

PACS numbers: 98.70.Sa, 95.55.Vj

Introduction — The sources of ultra-high-energy cosmic rays (UHECRs; cosmic-ray energy $E_{CR} \gtrsim 10^{18}$ eV) remain unidentified [1]. The majority of the candidate objects are extra-Galactic, such as Active Galactic Nuclei (AGN) [2–6], γ -ray bursts [7–13], and starburst galaxies [14–19]. UHECR interactions with ambient photons and matter at sources generate astrophysical neutrinos with 5% of the parent UHECR energy, on average [20–22]. Thus, a substantial fraction of these Extremely High-Energy (EHE) astrophysical neutrinos is expected to have an energy above 10^7 GeV. Moreover, neutrinos with energies above $\sim 10^7$ GeV are expected to be produced in the interactions between the highest-energy cosmic rays and background photons in the universe [23]. In the following we refer to the neutrinos produced in these interactions as cosmogenic neutrinos [24]. These astrophysical and cosmogenic EHE neutrinos can constitute key messengers identifying currently unknown cosmic accelerators, possibly in the distant universe, because their propagation is not influenced by background photon or magnetic fields.

In this Letter, we report results of an analysis of seven years of IceCube data obtained in the search for diffuse neutrinos with energies larger than 5×10^5 GeV. The current analysis is optimized in particular for the neutrinos with energies above 10^7 GeV, which is higher in energy than the other IceCube analyses [25, 26]. The analysis described here is based on data taken between April 2008 and May 2015, corresponding to 2426 days of effective livetime. This is approximately three times more data than the previous IceCube EHE neutrino search based on two years of data [27]. No cosmogenic neutrino candidate was observed in that study, but two PeV events were detected [28]. Stringent limits were placed on cosmogenic neutrino fluxes, and it was shown that astrophysical objects with emission rates per comoving space density as a function of redshift $\Psi_s(z)$ following a strong cosmological evolution, such as Fanaroff-Riley type-II (FR II) radio galaxies, are disfavored as highest-energy cosmic-ray sources.

Data selection and analysis — IceCube is a cubic-kilometer deep-underground Cherenkov neutrino detector located at the South Pole [29], which is designed to measure neutrinos with energies above 10^2 GeV. The construction of the IceCube detector was completed in December 2010. The array comprises 5160 optical sensors [30, 31] on 86 vertical strings distributed over a 1-

km³ instrumented ice volume at 1450–2450 m depth. Additional particle shower sensors at the surface constitute the IceTop air shower array [32]. In 2008–2009, 2009–2010, and 2010–2011, 40, 59, and 79 strings out of 86 were operational. Since 2011, IceCube has been recording data using the completed array.

The primary background in this analysis consists of downward-going muon bundles composed of a large number of muons produced in cosmic-ray interactions in the atmosphere. This background was simulated using the CORSIKA package [33] with the SIBYLL [34] hadronic interaction model. The secondary background is atmospheric neutrinos produced by the decay of charged mesons from cosmic-ray interactions in the atmosphere. The atmospheric neutrino simulation was generated by the IceCube neutrino-generator program based on the ANIS code [35]. At energies above $\sim 10^6$ GeV, prompt atmospheric neutrinos from short-lived heavy meson decays are expected to dominate over conventional atmospheric neutrinos from pion and kaon decays. While a flux of prompt atmospheric neutrinos must exist, it has not been experimentally observed. The conventional atmospheric neutrino model from [36], and the prompt model presented in [37] both incorporating the cosmic-ray knee model given in [38] are included in the background estimation. An updated calculation [39] of the prompt flux [37] predicts a reduced prompt flux by a factor of ~ 2 . The experimental data agree well with lower energy background predictions [27]. Cosmogenic and astrophysical neutrinos are simulated using the JULIET package [40] as in our earlier work [27].

The majority of atmospheric backgrounds deposit less energy in IceCube than the EHE neutrino signal. We reject most of the background by cutting events with low energy deposition. The number of observed Cherenkov photons is used as a proxy for the deposited energy. The majority of the background is removed by requiring that the measured Number of PhotoElectrons (NPE) is larger than a zenith angle-dependent threshold. The reconstructed zenith angle is obtained using a χ^2 fit to a simple track hypothesis [41]. The quality of the reconstruction is evaluated via the $\chi^2_{\text{track}}/ndf$ where ndf is the number of degrees of freedom. The selection threshold is optimized for the cosmological neutrino model [42] and kept constant for each detector configuration. The criteria are qualitatively equivalent to those used in [27], with details given in the Supplemental Material [43]. Events

FIG. 1. (Color online) Solid angle and time integrated exposure from April 2008 through May 2015 as a function of neutrino energy by flavor and flavor sum, including neutrino absorption effects in the Earth. The sharp peaked structure at 6.3×10^6 GeV for electron neutrinos is due to the Glashow resonance [50]. The Auger exposure [51] is included for reference.

with more than a single IceTop hit in the time interval of $-1\mu\text{s} \leq t_{ca} \leq 1.5\mu\text{s}$ are rejected. Here, t_{ca} is the time when the reconstructed downward-going track is at the closest approach to the IceTop optical sensors. The exposure of this analysis for each neutrino flavor is shown in Fig. 1 along with the summed exposure.

The background event rate induced by the atmospheric muons and neutrinos is reduced from ~ 2.8 kHz trigger-level rate to $0.064^{+0.023}_{-0.039}$ events per 2426 days of livetime. The expected event rates for cosmogenic and astrophysical models are shown in Tables I and II, respectively. Only electron and muon neutrinos are produced when UHECRs interact with photons or matter. As a result of flavor oscillation, $\nu_e : \nu_\mu : \nu_\tau = 1:1:1$ on Earth, assuming the standard full pion decay chain of neutrino production [21, 44, 45]. This is compatible with TeV-PeV flavor ratio measurements [46–49]. The neutrino distributions are summed over the three flavors. Equal neutrino and anti-neutrino fluxes, indistinguishable in IceCube, are assumed.

Two events were observed in the present 2426-day IceCube sample. The best estimates of the deposited energy are $(7.7 \pm 2.0) \times 10^5$ GeV and $(2.6 \pm 0.3) \times 10^6$ GeV, in the form of a spherical particle shower and an upward-moving track at a zenith angle of 101° [52], respectively. Three previously observed PeV events [28, 53] do not pass the current event selection, due to the increased NPE threshold for events with $\chi^2_{\text{track}}/\text{ndf} \geq 80$.

The sample satisfying the selection criteria is analyzed using the binned Poisson Log-likelihood ratio (LLR) method [54]. The events are binned in both the reconstructed zenith angle and the energy proxy, with only the energy proxy information being used for events with large $\chi^2_{\text{track}}/\text{ndf}$. The zenith angle and energy proxy used

in the LLR test are the results of refined reconstruction using a maximum likelihood method [55, 56]. The hypothesis that the two observed events are of atmospheric origin is tested using an ensemble of pseudo-experiment trials to derive the LLR test statistic distribution. The test rejects the atmospheric background-only hypothesis with a p-value of 0.014% (3.6σ). Furthermore, the hypothesis that the two events are of cosmogenic origin is rejected with a p-value of 0.3%, because of the low observed deposited energy and the absence of detected events at higher energy. However, the observations are compatible with a generic astrophysical E^{-2} power-law flux with a p-value of 92.3%. The energy deposited and the zenith angles of the two observed events are better described by a neutrino spectrum softer than the spectrum of $\geq 10^8$ GeV neutrinos, which experience strong absorption effects during their propagation through the Earth. This observation allows us to set an upper limit on a neutrino flux extending above 10^7 GeV. The limits also are derived using the LLR method. Cosmogenic neutrino models are tested by adding an unbroken E^{-2} flux without cutoff as a nuisance parameter to explain the observed two events.

The systematic uncertainties are estimated similarly to the previous publication [27]. The primary sources of uncertainty are simulations of the detector responses and optical properties of the ice. These uncertainties are evaluated with *in-situ* calibration system using a light source and optical sensor sensitivity studies in the laboratory. Uncertainties of $^{+13\%}_{-42\%}$ and $^{+2\%}_{-7\%}$ are estimated for the number of background and signal events, respectively. In addition, uncertainties of -11% are introduced to the neutrino-interaction cross-section based on CTEQ5 [57] calculated as [58] and $+10\%$ by the photonuclear energy losses [60]. The uncertainty on the neutrino-interaction cross section is from [59]. The uncertainty associated with photonuclear cross section is estimated by comparing the current calculation with the soft-component-only model. Uncertainty of $^{+34\%}_{-44\%}$ associated with the atmospheric background is also included. The error is dominated by the experimental uncertainty of CR spectrum measurements ($\pm 30\%$) [1, 61], theoretical uncertainty on the prompt flux calculation [37], and the primary CR composition. All the resultant limits presented in this Letter include systematic uncertainties. Taking the maximally and minimally estimated background and signal distributions in a 1σ error range by adding systematic uncertainties in quadrature, each signal and background combination results in an upper limit. The weakest limit is taken as a conservative upper limit including systematic uncertainties. The uncertainty is energy-dependent and, thus, it is model-spectrum-shape dependent. Model-dependent limits are generally weakened by $\sim 20\%$ and $\sim 30\%$ for cosmogenic and astrophysical-neutrino models, respectively.

FIG. 2. (Color online) Model-dependent 90% confidence-level limits (solid lines) for (upper panel) proton cosmogenic-neutrino predictions (dashed lines) from Ahlers [42] and Kotera [64] and (lower panel) astrophysical neutrino fluxes from AGN (BLR) models of Murase [81] and Padovani (long dashes: $Y_{\nu\gamma} = 0.8$, short dashes: $Y_{\nu\gamma} = 0.3$) [82], and Fang pulsar model [84]. The range of limits indicates the central 90% energy region. Two lines of the Ahlers model represent different threshold energy of the extragalactic UHECR component. The deviation of the Kotera and Ahlers models below 10^8 GeV is due to different models of the extragalactic background light assumed for the calculation. The wide energy coverage of the current analysis (Fig. 1) allows a stringent model-dependent limit to be placed for both cosmogenic and astrophysical models.

Cosmogenic neutrinos — We tested cosmogenic neutrino models. Aside from the primary composition dependence, the cosmogenic neutrino rates in the current analysis depend significantly on the UHECR source evolution function that characterize the source classes. Table I represents the p-values and associated 90%-CL limits for cosmogenic models. The models from [42] are constructed in such a manner that the cosmogenic γ -ray emission from the decays of π^0 produced by the interactions of UHECRs with the cosmic microwave background (CMB) is consistent with the Fermi-LAT measurements of the diffuse extragalactic γ -ray background [62, 63]. Our constraints on these models imply that the majority of the observed γ -ray background is unlikely to be of cosmogenic origin.

Limits on cosmogenic neutrino models [64, 65] using two classes of source-evolution functions are presented in Table I. One evolution function is the star formation rate (SFR) [66], which is a generic measure of structure formation history in the universe, and the other is that of FR II radio-loud AGN [67, 68]. The cosmogenic models assuming FR II-type evolution have already been constrained by the previous study [27]. In addition, these

FIG. 3. (Color online) Constraints on UHECR source evolution model and all flavor E^{-2} power-law flux model parameters. The colored areas represent parameter space excluded by the current analysis. (Top) Cosmogenic flux parameters m and z_{\max} of UHECR-source cosmological evolution function of the form $\psi_s(z) \propto (1+z)^m$, assuming proton-dominant UHECR primaries with only the CMB as the background photon field. A semi-analytic formulation [75], with the injected proton spectrum of $E^{-2.5}$ up to 6×10^{11} GeV, is used to estimate the neutrino flux. The boxes indicate approximate parameter regions for SFR [66] and FR II (-A [67] and -B [68]) neglecting the minor far-redshift contributions. (Bottom) Upper limits on E^{-2} power-law neutrino flux normalization ϕ_0 and spectral cutoff energy E_{ν}^{cut} .

strong evolution models may conflict with the observed γ -ray background [42, 69, 70]. The current analysis not only strongly constrains the FR II-type but also is beginning to constrain the parameter space where SFR drives UHECR source evolution. The predicted neutrino spectra and the corresponding model-dependent limits are presented in Fig. 2. When the primaries are heavy nuclei, photodisintegration is more likely than pion production, hence the flux of cosmogenic muon neutrinos is suppressed [64, 71–74].

Thus the limit on the proton composition cosmogenic models could also be considered as the limit on the proton fraction of a mixed-composition UHECR model for the given evolution model.

A more generic scanning of parameter space for the source evolution function, $\Psi_s(z) \propto (1+z)^m$, up to the maximum source extension in redshift $z \leq z_{\max}$, was also performed using an analytical parameterization [75]. Because only the CMB is assumed as the target photon field in the parameterization, the limits are systematically weaker than that on the models that include extragalac-

FIG. 4. (Color online) All-flavor-sum neutrino flux quasi-differential 90%-CL upper limit on one energy decade E^{-1} flux windows (solid line). The limits are derived using a log-likelihood ratio method. The median null observation limit (sensitivity) is also shown (dashed line). Cosmogenic-neutrino model predictions (assuming primary protons) are shown for comparison: Kotera *et al.* [64], Ahlers *et al.* [42], and an astrophysical neutrino model from Murase *et al.* [81]. Model-independent differential limits on one energy decade E^{-1} flux from Auger [51] and ANITA-II [86] with appropriate normalization are also shown. A model-dependent upper limit on an unbroken E^{-2} power-law flux from the current analysis ($E_\nu^2 \phi < 9.2 \times 10^{-9}$ GeV/cm² s sr) is shown for reference (dotted line).

tic background light, such as infrared and optical photons, with the given evolution parameters. The resultant exclusion contour is shown in the upper panel of Fig. 3. Each point represents a given cosmogenic-neutrino model — normalized by fitting the UHECR spectrum to data [75] — and the contour represents the exclusion confidence limit calculated using the LLR method. The UHECR spectrum dependence of cosmogenic neutrino model is also studied in [76]. Our results disfavor a large portion of the parameter space where $m \geq 3.5$ for sources distributed up to $z_{\text{max}} = 2$. These constraints imply that the sources of UHECRs seem to evolve more slowly than the SFR. Otherwise, a proton-dominant composition at the highest energies, in particular the dip model [77], is excluded [78], as studied also in [70, 79, 80].

Astrophysical neutrinos — We tested astrophysical neutrino models for the UHECR sources. One of the advantages of studying astrophysical neutrino models is that not only proton-dominant, but also mixed- or heavy-composition UHECR models can be tested with IceCube.

The results of the model tests are listed in Table II, and the limits are shown in the lower panel of Fig. 2.

The AGN models relate the neutrino emission rates in each source with the observed photon fluxes using phenomenological parameters, such as the baryon loading factor ξ_{cr} [81] and the neutrino-to- γ -ray intensity ratio $Y_{\nu\gamma}$ [82]. As the neutrino flux scales linearly with these parameters, the limits can be interpreted as constraints on the parameters, as listed in Table II. The observed UHECR generation rate around 10^{10} GeV ($\sim 10^{44}$ erg Mpc⁻³ yr⁻¹) requires the loading factor ξ_{cr} to be around 3 and 100 for UHECR spectral indices $s = 2.0$ and 2.3, respectively [81]. The current constraints on ξ_{cr} are comparable or slightly below these required values. This indicates that AGN inner jets are less likely to be a major source of the UHECRs, regardless of the observed UHECR compositions. A consistent but weaker limit on these models is also obtained from an analysis searching for the neutrino signal excess in the direction of blazar populations [83]. Rapidly spinning pulsars may also be capable of accelerating nuclei to 10^{11} GeV [84]. They are also disfavored as UHECR sources if they have cosmological evolution stronger than SFR. As shown in Fig. 2, provided a flat neutrino spectrum in the UHECR source is assumed, astrophysical neutrino spectra are generally predicted to be described by a hard power law [85]. These spectra continue up to a cutoff energy determined by the maximal acceleration energy of the source. Figure 3 provides a generic constraint on these astrophysical fluxes as an exclusion region in the parameter space for E^{-2} power-law neutrino flux normalization ϕ_0 and spectral cutoff energy E_ν^{cut} . It indicates that $E^2 \phi_0 \geq 6 \times 10^{-9}$ GeV cm⁻² s⁻¹ sr⁻¹ is disfavored for neutrino fluxes extending above 10^9 GeV, such as the UHECR source models.

Differential limit — A quasi-differential 90%-CL limit is presented in Fig. 4 using the LLR method, considering the two observed events. Each point on the solid line is the result of an independent hypothesis test for a decade-wide E^{-1} power-law flux as a signal model, representing a 90%-CL upper limit. The median null observation limit (sensitivity) is also presented. The limit for an E^{-2} flux ($E_\nu^2 \phi < 9.2 \times 10^{-9}$ GeV/cm² s sr) in the central 90% energy region between 1.0×10^6 and 4.0×10^9 GeV is shown for reference.

Summary — Analysis of IceCube data results in the largest exposure to date in search for the neutrino flux above 10^7 GeV up to 3×10^{10} GeV. The non-observation of neutrino events with deposited energy larger than a few PeV in seven years of IceCube data places a serious constraint on cosmogenic and astrophysical neutrino models. The restrictions on the cosmological evolution of UHECR sources and the model-dependent constraints on the source classes reported herein are the strongest constraints on the origin of the highest-energy cosmic rays above the ankle achieved via neutrino astronomy.

ν Model	Event rate per livetime	p-value	MRF
Kotera <i>et al.</i> [64]			
SFR	$3.6^{+0.5}_{-0.8}$	$22.3^{+10.8\%}_{-3.9\%}$	1.44
Kotera <i>et al.</i> [64]			
FRII	$14.7^{+2.2}_{-2.7}$	$<0.1\%$	0.33
Aloisio <i>et al.</i> [65]			
SFR	$4.8^{+0.7}_{-0.9}$	$7.8^{+6.8\%}_{-1.8\%}$	1.09
Aloisio <i>et al.</i> [65]			
FRII	$24.7^{+3.6}_{-4.6}$	$<0.1\%$	0.20
Yoshida <i>et al.</i> [87]			
$m = 4.0, z_{max} = 4.0$	$7.0^{+1.0}_{-1.0}$	$0.1^{+0.4\%}_{-0.1\%}$	0.37
Ahlers <i>et al.</i> [42]			
best fit, 1 EeV	$2.8^{+0.4}_{-0.4}$	$9.5^{+6.5\%}_{-1.6\%}$	1.17
Ahlers <i>et al.</i> [42]			
best fit, 3 EeV	$4.4^{+0.6}_{-0.7}$	$2.2^{+1.3\%}_{-0.9\%}$	0.66
Ahlers <i>et al.</i> [42]			
best fit, 10 EeV	$5.3^{+0.8}_{-0.8}$	$0.7^{+1.6\%}_{-0.2\%}$	0.48

TABLE I. Cosmogenic neutrino model tests: Expected number of events in 2426 days of effective livetime, p-values from model hypothesis test, and 90%-CL model-dependent limits in terms of the model rejection factor (MRF) [88], defined as the ratio between the flux upper limit and the predicted flux.

ν Model	Event rate per livetime	p-value	MRF
Murase <i>et al.</i> [81]			
$s = 2.3, \xi_{CR}=100$	$7.4^{+1.1}_{-1.8}$	$2.2^{+9.9\%}_{-1.4\%}$	0.96 ($\xi_{CR} \leq 96$)
Murase <i>et al.</i> [81]			
$s = 2.0, \xi_{CR}=3$	$4.5^{+0.7}_{-0.9}$	$19.9^{+20.2\%}_{-9.2\%}$	1.66 ($\xi_{CR} \leq 5.0$)
Fang <i>et al.</i> [84]			
SFR	$5.5^{+0.8}_{-1.1}$	$7.8^{+14.4\%}_{-3.7\%}$	1.34
Fang <i>et al.</i> [84]			
uniform	$1.2^{+0.2}_{-0.2}$	$54.8^{+1.7\%}_{-2.7\%}$	5.66
Padovani <i>et al.</i> [82]			
$Y_{\nu\gamma} = 0.8$	$37.8^{+5.6}_{-8.3}$	$<0.1\%$	0.19 ($Y_{\nu\gamma} \leq 0.15$)

TABLE II. Astrophysical neutrino model tests: Same as Table I. The flux normalization scales linearly for AGN models with the assumed baryonic loading factor ξ_{CR} for Murase FSRQ (broad-line region) [81] or neutrino-to- γ ratio $Y_{\nu\gamma}$ for Padovani BL Lac [82] models. A power-law proton UHECR spectrum with index s is assumed in the FSRQ model. The corresponding parameters for these models to explain the measured IceCube neutrino flux in TeV-PeV range [53] are excluded by more than 99.9% CL.

The detection of cosmogenic neutrinos from sources with weak or no evolution, and of heavy-composition UHECRs requires a larger scale detector. Cost-effective radio Askaryan neutrino detectors, such as ARA [89] or ARIANNA [90], therefore would be an important future option.
