We use a first-principles density functional theory approach to calculate the shift current and linear absorption of uniformly illuminated single-layer Ge and Sn monochalcogenides. We predict strong absorption in the visible spectrum and a large effective three-dimensional shift current (∼100 μA/V²), larger than has been previously observed in other polar systems. Moreover, we show that the integral of the shift-current tensor is correlated to the large spontaneous effective three-dimensional electric polarization (∼1.9 C/m²). Our calculations indicate that the shift current will be largest in the visible spectrum, suggesting that these monochalcogenides may be promising for polar optoelectronic devices. A Rice-Mele tight-binding model is used to rationalize the shift-current response for these systems, and its dependence on polarization, in general terms with implications for other polar materials.

Introduction: The shift current is a dc current generated in a material under uniform illumination [1–4], and gives rise to such phenomena as the bulk photovoltaic effect (BPVE) [1]. A necessary condition for the BPVE in a material is the lack of inversion symmetry. Interestingly, in the BPVE, the resulting photovoltage is not limited by the band gap energy, and a junction or interface is not required to generate a current. These properties of the BPVE motivate great interest in possible optoelectronic applications of noncentrosymmetric systems, and they have been suggested to play a role in emerging functional materials, including hybrid halide perovskites [5].

The BPVE is much less studied in two-dimensional (2D) materials [6–8]. 2D materials represent the ultimate scaling in thickness with mechanical, optical and electronic properties unique relative to their bulk counterparts. For example, single-layer group-IV monochalcogenides GeS, GeSe, SnS and SnSe are actively being investigated [9–17] due to their band gaps and large carrier mobilities suitable for optoelectronics. Centrosymmetric in the bulk, the monochalcogenides lack inversion symmetry in single-layer form, allowing for the emergence of a spontaneous polarization and a BPVE. Although broken inversion symmetry is necessary for a non-zero shift current, the relationship between shift current and polarization at a given frequency is complex and depends on the degree of asymmetry and spatial localization of the valence and conduction states [5]. On the other hand, the shift-current spectra integrated over frequency is clearly correlated to polarization, as shown in this manuscript.

In this Letter we use first principles density functional theory methods, supplemented by a tight-binding model, to predict and understand the spontaneous polarization and BVPE in single-layered monochalcogenides.
FIG. 2. (Color online) Shift-current spectra (a), shift vector integrated over $k$ (b) and linear absorption (c) of single-layer GeS. The large in-plane shift-current response in the visible range is dominated by the shift vector and corresponds to the large absorption along $zz$ and $yy$.

that include at least 10 Å of vacuum between layers. Our relaxed lattice parameters are shown in Table I and agree with previous work [10] (see SI for details, which includes Ref. [23]).

Bulk monochalcogenide crystals MX ($M=\text{Ge,Sn}$ and $X=\text{S,Se}$) are orthorhombic with point group $mmm$ and space group $Pnma$ (No. 62). They consist of van der Waals-bonded double layers of metal monochalcogenide atoms in an armchair arrangement. The space group of the bulk crystal contains eight symmetries including a center of inversion which prevents spontaneous electric polarization and BPVE. Upon exfoliation, the resulting single “double layer” primitive cell has four atoms. In this work, the layers are chosen to be oriented perpendicular to the $x$ axis as shown in Fig. 1a. The single-layer structure has four symmetries, including a two-fold rotation with respect to $z$ (plus translation), $2[001]+(1/2,0,1/2)$, which determines the direction of the in-plane spontaneous polarization of the layer along the $z$ axis. In addition, the 2D-system has two mirror symmetries with respect to $x$ and $y$, $m[100]+(1/2,1/2,0)$ and $m[010]+(0,1/2,0)$. Hence its point group, which determines the non-zero components of the optical response tensors, is $mm2$.

As a consequence of the mirror symmetries with respect to the $x$ and $y$ axis of a single monochalcogenide layer, all the cross-components terms of the imaginary part of the dielectric function, $\epsilon^{ab}_2$, vanish together with the tensor components $xzx, zzy, xzz, yxx, yyy$ and $yzz$ of the shift current. Only seven components are symmetry-allowed [24]: $xxx, zyy, zzz, yyz$ and $xzx$, as well as components obtained by interchanging the last two indices. Symmetry, however, does not dictate the magnitude of the response in each direction, and consequently we compute the matrix elements below.

**Spontaneous polarization.** We calculate the spontaneous polarization of single-layer chalcogenides using the modern theory of polarization [25, 26], as implemented in ABINIT. We first identify an adiabatic path between the ground state and a centrosymmetric geometry with, in this case, zero polarization. We parametrize the atomic displacements along a path between these geometries (Fig. 1b, 1d) with $\lambda$ as $R^i(\lambda) = R^i_0 + \lambda(R^f_j - R^i_0)$, where $R^i_0$ ($R^f_j$) is the initial (final) position of $i$th atom in the centrosymmetric (non-centrosymmetric) structure. We calculate the minimum-energy path between the $\pm P_0$ configurations, as detailed in the SI. The minimal energy path is indistinguishable from the linear path used here. The polarization for various 2D monochalcogenides has also been theoretically studied recently [13, 17, 27–32]. Our adiabatic polarization path, as shown schematically in Fig. 1b and (d). Table I shows the spontaneous electric polarization per unit area, $P_0$, and an effective 3D polarization assuming an active single-layer thickness $a = 2.6$ Å. Interestingly, GeSe has a significantly higher effective 3D polarization, 1.9 C/m$^2$, than most prototypical ferroelectrics, e.g., $0.0028$ C/m$^2$ in CaMn$_2$O$_4$ [33], $0.26$ C/m$^2$ in BaTiO$_3$ [34, 35], $0.37$ C/m$^2$ in KNb$_3$O$_7$ [36] and $0.9$ C/m$^2$ in BiFeO$_3$ [37, 38]. The energy barriers, provided in Table I, are much larger than room temperature. However, since reorientation under an applied electric field is often facilitated by domain wall motion, future experiments are necessary to conclusively demonstrate ferroelectric switching behavior.

**Optical absorption and shift current.** One notable feature of single-layer monochalcogenides is their promising band gaps energies in the visible range [12, 18, 19]. In Table I, we show the computed DFT-PBE gaps, which are a good estimate of the corresponding optical gaps. Although in principle ab initio many-body perturbation theory (MBPT) would be a more rigorous approach to optical gaps, in this case, we expect the PBE single-particle gaps to be indicative in this case since excitonic effects, as large as 1 eV in GeS [19], can fortuitously cancel the well-known tendency of PBE to underestimate the transport gap. In Sn-based materials, the PBE gaps are smaller by ~0.5 eV than in MBPT (see Table I), and hence the responses are redshifted and should be treated with more caution. In addition, since exciton formation can enhance shift current at exciton resonances [39], strong excitonic effects in monochalcogenides could lead to even larger shift currents.

We calculate the imaginary part of the dielectric function, $\epsilon^{ab}_2$, within the independent particle approximation. As shown in Fig. 2, the absorption is strong $\epsilon_2 \sim 50$, in the visible range of 1.5 to 3 eV, due to their direct or
The shift-current tensor is given by \[3\]

\[\sigma^{abc}(\omega, -\omega)\] the form describes the response. Following the analysis of Ref. [44], we interpret \(eR^{ab}(\omega)\) as a collective shift of polarization upon excitation.

The dc shift current is generated to second order in the shift-current response, as shown below.

The absorption and shift-current spectra are related by the velocity matrix elements \(r_{nm}\) entering Eq. 2, explaining why peaks in \(\varepsilon_2\) tend to correspond to peaks in the shift current spectra. To explore the relationship between \(\varepsilon_2^{bb}\) and \(\sigma^{abc}\), in Fig. 2b, we show the shift vector integrated over the Brillouin zone (BZ) [5, 44],

\[eR^{ab}(\omega) = e \int \frac{dk}{8\pi^3} \sum_{nm} f_{nm} R_{nm}^{ab} \delta(\omega_{nm} - \omega). \tag{3}\]

For the monochalcogenides, \(eR^{ab}(\omega)\) contains all features of \(\sigma^{abc}(\omega)\), and hence dominates the shift-current response. Following the analysis of Ref. [44], we interpret \(eR\) as a collective shift of polarization upon excitation, due to transitions from valence to conduction states with distinct center of mass [45]. Thus, wavefunction Berry phases play a fundamental role in the BPVE, which we further explore next.

**Polarization and shift current.** To understand the relation between \(\sigma^{abc}\) and \(P\), consider a short-circuit bulk ferroelectric illuminated by unpolarized light with a flat broad spectrum. The short-circuit current in the \(z\)-direction, \(I_{sc} = AE_z^2 \int d\omega(\varepsilon^{zz}(0; \omega, -\omega) + \varepsilon^{zz}(0; \omega, -\omega))\), is proportional to the integral of the shift current tensor. Here, the cross sectional area is \(A\) and the amplitude of the electric field is \(E_0\). To first non-vanishing order in \(\lambda\) both the polarization and the integral are linear in \(\lambda\), \(P(\lambda) = \partial_\lambda P(0) \lambda + \cdots\), \(\int \sigma^{abc}(\lambda) = (\int \partial_\lambda \sigma^{abc}(0)) \lambda + \cdots\), and hence proportional to each other.

In Fig. 3 we show the integral of the shift-current tensor over the frequency range (up to 6 eV) for GeS as...
a function of polarization along the adiabatic path of Fig. 1b. For small polarization, the integral grows linearly with polarization, as expected. However, for larger polarization there is non-monotonic behavior which we explain below with a tight-binding model. Notice that without the integral, the expansion coefficients become frequency dependent and the current could increase or decrease with polarization with no general relationship.

The Rice-Mele tight-binding model. As mentioned previously, the monochalcogenide layer has a $2[001]+(1/2, 0, 1/2)$ symmetry that transforms the the upper three atoms in Fig. 1b onto the lower three. This suggests there is an effective one-dimensional description of the armchair structure in the $z$ direction, and in fact, as we show below, the trends in the integral of the shift-current tensor along $z$ are captured by a simple model Rice-Mele (RM) model [46, 47]. The RM Hamiltonian is

$$H = \sum_i \left[ \left( \frac{t}{2} + \frac{1}{2} \delta \right) c_i^\dagger c_{i+1} + h.c. \right] + \left( -1 \right)^i \Delta c_i^\dagger c_i,$$

where $\delta$ parametrizes the structural distortion relative to the centrosymmetric structure, $\Delta$ the staggered on-site potential, and $c_i^\dagger$ is the creation operator for electrons at site $i$. Inversion symmetry is broken when both $\Delta \neq 0$ and $\delta \neq 0$, and preserved otherwise. For this two-band model Eq. 2 gives (see SI for more details),

$$\int d \omega \sigma_{zzz}(0; \omega, -\omega) = e^3 \int dk \frac{|v_{cv}|^2 R_{cv}}{4E^2},$$

where $R_{cv} = \partial \phi_{cv}/\partial k + A_{cc} - A_{cv}$ is the shift vector and is gauge invariant. $A_{nm} = i\langle u_n | \partial_k | u_m \rangle$ are the Berry connections, and $\phi_{nm}^b$ is defined by $r_{nm}^b = |r_{nm}^b| e^{-i\phi_{nm}^b}$, where $E(k)$ is the band dispersion and $v_{cv}$ is the matrix element of the velocity operator. The Rice-Mele model allows for a complete analytic solution for the optical response and these results will be presented elsewhere [48]. The polarization is $P(\delta) = \left( e^2/2\pi \right) \int dk \left( A_{cv}(k, \delta) - A_{cv}(k, 0) \right)$. The model has two independent parameters $\delta$ and $\Delta$. To make contact with the monochalcogenides, we set $t = 1$, and $\delta$ and $\Delta$ are related by the energy gap, $2\sqrt{\delta_0^2 + \Delta_0^2} = 1.9$ eV (for GeS). Choosing parameters $(t, [0, \delta_0], \Delta_0) = (1, [0, -0.87], 0.4)$ eV fits the $zzz$ ab-initio integral for GeS well and corresponds to a gap of 1.9 eV. The RM model polarization is $P_0 = P(\delta_0)$.

As the RM model is a good description of the integral of the shift-current tensor in monochalcogenides, we now explore the relation between polarization and shift current within this model. The integral of the shift-current tensor in Eq. 5 is determined by the competition between the shift vector and the velocity matrix elements $|v_{cv}|^2/4E^2 \equiv |r_{cv}|^2$. These in turn are controlled by $\delta$ and $\Delta$, which have opposing tendencies: whereas increasing $\Delta$ tends to localize charge at lattice sites, increasing dimerization $\delta$ moves the center of charge away from them (leading to an increase in polarization). We find that for $\delta \ll \Delta$, $R_{cv}$ is sharply peaked at $k = 0$ but $|v_{cv}|^2/4E^2$ peaks at $\pi/c$, and hence the integral is small. As $\delta$ increases, $R_{cv}$ and $|v_{cv}|^2/4E^2$ broaden, and the integral increases; the integral reaches a maximum at an optimum value, $\pm \delta_m$ which to lowest order in $\Delta$ is

$$\delta_m = \Delta + O(\Delta^3 \log \Delta),$$

where the polarization takes the value $P(\delta_m)$. For GeS, SeS and SnS $\delta_0 (-0.9, -0.5$ and $-0.6$ respectively) is relatively close to the optimal $\delta_m$ values of $-0.5$, $-0.5$ and $-0.6$ respectively, whereas for SnSe $\delta_m (0.4)$ is farthest from $\delta_0 (-0.2)$, see SI. Therefore, consistent with Refs. 7 and 5, the large shift-current in these monochalcogenides results from two competing factors, i.e., a large shift vector and large velocity matrix elements (linear absorption strength), both of which can be moduled with polarization (and therefore composition, structure, and external electric field).

Discussion and conclusions We have calculated the shift-current response and spontaneous electric polarization of a family single-layer monochalcogenides; MX where $M =$ Ge, Sn, and $X =$ S, Se. We find a large shift current and a large polarization compared with prototypical ferroelectric materials. The fact the maximum current occurs in the visible range highlights the potential of these materials for optoelectronic applications. Further, the large spontaneous polarization can serve as knob to engineer the photoresponse. The integral of the shift-current tensor over frequency is clearly dependent on polarization and by means of a RM model, we find an optimal value of polarization where the current is maximum.
BMF and TR made equal contributions. We thank J. Sipe, F. de Juan, S. Barraza-Lopez, S. Coh, R. A. Muniz, S. E. Reyes-Lillo for useful discussions. * These two authors contributed equally.

[41] Here we show that a single-layer monochalcogenide has a large shift current response, moreover in the SI we show that the response of a thick 3D array of slabs, characterized by the Glass coefficient [49], is also large.

[45] The integral of the shift-vector over \( k \), \( \mathbf{R} \) has been studied for complex ferroelectric materials, such as BiTiO\(_3\) and PbTiO\(_3\) in Ref. 5, where the relation of \( \mathbf{R} \) and \( \sigma^{abc} \) was found dependent on the nature of the initial and final states in the transition, as discussed more thoroughly in
the SL.
