We present a state-of-the-art calculation of the isovector quark helicity Bjorken- x distribution in the proton using lattice-QCD ensembles at the physical pion mass. We compute quasi-distributions at proton momenta $P_z \in \{2.2, 2.6, 3.0\}$ GeV on the lattice, and match them systematically to the physical parton distribution using large-momentum effective theory (LaMET). We reach an unprecedented precision through high statistics in simulations, large-momentum proton matrix elements, and control of excited-state contamination. The resulting distribution with combined statistical and systematic errors is in agreement with the latest phenomenological analysis of the spin-dependent experimental data; in particular, $\Delta\bar{u}(x) > \Delta\bar{d}(x)$.

Understanding the spin structure of the proton is a challenging frontier problem in modern physics. Some of the most studied physical observables are the parton helicity distributions $\Delta q(x)$ and $\Delta g(x)$, which describe the number densities of polarized partons (quarks and gluons) with momentum fraction x in a longitudinally polarized proton. Decades of polarized deep inelastic scattering (DIS) and semi-inclusive DIS (SIDIS) data at a wide range of kinematics have greatly improved our knowledge of these distributions. Significant progress has also been made in recent years in polarized proton-proton collisions at the Relativistic Heavy-Ion Collider (RHIC). Groups such as DSSV14 [1], NNPDFpol1.1 [2], and JAM17 [3] have used the available experimental data to yield the phenomenological helicity-dependent distributions. In the future, the kinematic coverage for spin-dependent parton distribution functions (PDFs) is expected to be greatly expanded with new data on DIS and SIDIS from Jefferson Lab 12-GeV [4] and a future Electron-Ion Collider (EIC) [5].

Lattice gauge theory allows *ab initio* calculations of the proton spin structure from the fundamental theory of strong interaction: quantum chromodynamics (QCD). The lowest moments of the polarized quark distribution are matrix elements of local operators, and have been

studied extensively using lattice calculations (see [6] for a review). On the other hand, x -dependent PDFs have until recently defied theoretical attempts, fundamentally because PDFs are defined through the matrix elements of lightcone correlations, whereas the lattice approach is intrinsically Euclidean. Large-momentum effective theory (LaMET) [7–11] recently provided a breakthrough in calculation of the x -dependence of PDFs using lattice QCD. On the lattice, one can calculate the matrix elements of Euclidean observables in a large-momentum hadron state (often called “quasi-PDFs” in the study of parton distributions), which can be used to extract the nonperturbative lightcone dynamics through factorization and matching.

There has been much progress in the last few years in applying LaMET to calculate lightcone physics (see Ref. [12]) for a more complete list of references). In particular, the renormalization properties of the quasi-PDF operators and nonperturbative renormalization (NPR) on lattice have been understood and implemented [13–21]. Progress also has been made in studying spin-dependent lightcone physics in LaMET. Our pioneering exploratory calculation on quark helicity PDFs [22] was done at pion mass $M_\pi \approx 310$ MeV, with the largest proton momentum around 1.3 GeV. A later calculation by ETMC [23] at slightly heavier pion mass showed similar results. The full matching calculations and mass corrections were reported in [24]. Helicity-distribution calculations in regularization-independent momentum-

subtraction (RI/MOM) scheme and NPR at physical pion mass were first reported by us [25], and more recently with high statistics by ETMC [26].

In this paper, we report a state-of-the-art calculation at physical pion mass on the isovector quark helicity PDF, $\Delta u(x) - \Delta d(x)$, in the proton. Large-momentum (up to 3.0 GeV) proton sources have been employed to suppress high-twist contributions to quasi-PDFs. The proton matrix elements are renormalized in RI/MOM scheme, along with a matching formula to connect the RI/MOM quasi-PDF to the physical PDF in $\overline{\text{MS}}$ scheme [12, 27]. Six source-sink separations in combination with multiple-state analysis help to remove excited-state contamination from the proton state. In the moderate- to large- x region, the final result with combined statistical and systematic errors shows a significant improvement compared to previous lattice studies and is consistent with the global analyses by NNPDF and JAM groups. We also see evidence that $\Delta \bar{u}(x) > \Delta \bar{d}(x)$, as found in experimental data.

To calculate the quark helicity PDFs in LaMET, we start by computing a quasi-PDF on a lattice with spacing a ,

$$\Delta \tilde{q}(x, P_z, a) = \int_{-\infty}^{\infty} \frac{P_z dz}{2\pi} e^{ixP_z z} \frac{1}{2P_0} \langle PS | \hat{O}(z, a) | PS \rangle \quad (1)$$

where $P_\mu = (P_0, 0, 0, P_z)$ and $S_\mu = (P_z, 0, 0, P_0)$ are the proton four-momentum and longitudinal polarization vectors, respectively. The nonlocal Euclidean operator is $\hat{O}(z, a) = \bar{\psi}_q(z) \gamma^z \gamma_5 U(z, 0) \psi_q(0)$ with the Wilson line $U(z, 0) = P \exp(-ig \int_0^z dz' A_z(z'))$ and subscript $q = (u, d, s, \dots)$ as a flavor index. Here, we consider the isovector combination, $\Delta \tilde{u} - \Delta \tilde{d}$, so that the disconnected contributions on lattice cancel.

$\hat{O}(z, a)$ has both power and logarithmic divergences as $a \rightarrow 0$, and for the isovector combination, all divergences have been shown to factorize [17–19]. To achieve high precision in matching, a NPR for the lattice operators is used to define the continuum limit of the quasi-PDF matrix elements. Following the RI/MOM scheme advocated in Refs. [20, 27], we introduce a z -dependent renormalization factor $Z(z, p_z^R, \mu_R, a)$ defined on the lattice in an off-shell quark state in Landau gauge with z -component momentum p_z^R and subtraction scale μ_R . The renormalized matrix element of $\tilde{h}(z, P_z, a) = (1/2P_0) \langle PS | \hat{O}(z, a) | PS \rangle$ in coordinate space,

$$\tilde{h}_R(z, P_z, p_z^R, \mu_R) = Z^{-1}(z, p_z^R, \mu_R, a) \tilde{h}(z, P_z, a), \quad (2)$$

has a well defined continuum limit as $a \rightarrow 0$.

Following the framework described in Refs. [27, 28], the matching between the renormalized quasi-PDF $\Delta \tilde{q}_R(x, P_z, p_z^R, \mu_R)$ and the physical PDF $\Delta q(y, \mu)$ at

scale μ is

$$\Delta \tilde{q}_R(x, P_z, p_z^R, \mu_R) = \int_{-1}^1 \frac{dy}{|y|} C\left(\frac{x}{y}, r, \frac{yP_z}{\mu}, \frac{yP_z}{p_z^R}\right) \Delta q(y, \mu) + \mathcal{O}\left(\frac{M^2}{P_z^2}, \frac{\Lambda_{\text{QCD}}^2}{P_z^2}\right), \quad (3)$$

where $r = \mu_R^2/(p_z^R)^2$, M is the proton mass, and the antiquark distribution $\Delta \bar{q}(y, \mu) \equiv \Delta q(-y, \mu)$ falls in the region $-1 < y < 0$. The matching coefficient C at one-loop level using minimal projection in the $\overline{\text{MS}}$ scheme can be found in Ref. [12].

We perform lattice calculations of the bare isovector quark helicity quasi-PDF using clover valence fermions on an ensemble of 884 gauge configurations with lattice spacing $a = 0.09$ fm, box size $L \approx 5.8$ fm, and with pion mass $M_\pi \approx 135$ MeV and $N_f = 2 + 1 + 1$ (degenerate up/down, strange and charm) flavors of highly improved staggered dynamical quarks (HISQ) [29] generated by MILC Collaboration [30]. The gauge links are one-step hypercubic (HYP)-smeared [31] to suppress the discretization effects. The clover parameters are tuned to recover the lowest pion mass of the staggered quarks [32–35]. We use multigrid algorithm [36, 37] in Chroma software package [38] to speed up the clover fermion inversion of the quark propagator at physical pion mass, allowing a high-statistics calculation.

We use Gaussian momentum smearing [39] for the quark field $\psi(x) + \alpha \sum_j U_j(x) e^{ik\hat{e}_j} \psi(x + \hat{e}_j)$, where $k = 6$ is the input momentum parameter, $U_j(x)$ are the gauge links in the j direction, and α is a tunable parameter as in traditional Gaussian smearing. Such a momentum smearing is designed to increase overlap of the lattice sources with the ground-state proton of the desired momenta, which allows us to reach higher-momentum states than was previously possible [25]. This calculation employs sources with $\vec{P} = \{0, 0, n\frac{2\pi}{L}\}$, with $n \in \{10, 12, 14\}$, which correspond to 2.2, 2.6 and 3.0 GeV proton momenta, respectively.

We investigate the excited-state contamination in the proton matrix elements by fitting data with different source-sink separations. As the proton momentum increases, we anticipate stronger excited-state contamination since the excitation spectrum gets compressed. We measure the proton matrix elements with six source-sink separations, $t_{\text{sep}} \in \{0.54, 0.72, 0.81, 0.90, 0.99, 1.08\}$ fm with the number of measurements $\{16, 32, 32, 64, 64, 128\}$ k, respectively. We use four two-state fits [35] to remove excited-state systematics among these source-sink separations by varying the number of excited-state matrix elements (“two-sim” and “two-simRR”) and the smallest t_{sep} in the analysis. Fit-1 uses the “two-simRR” analysis [35], which includes two additional matrix elements related to excited states. To counter the increase of degrees of freedom, we use all six separations; the fit uses only the largest five separations as Fit-2. Fit-3 uses the “two-sim” analysis

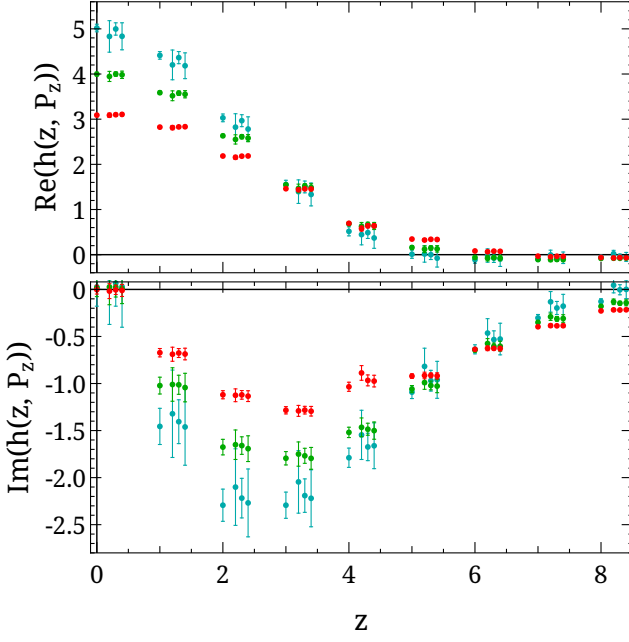

FIG. 1. The real (top) and imaginary (bottom) parts of the bare proton matrix elements for the isovector quark helicity as functions of z at all three momenta (2.2, and 2.6 and 3.0 GeV indicated by red, green and blue, respectively). Their kinematic factors have been omitted to enhance visibility by separating the small- z matrix elements. At a given positive z value, the data are slightly offset to show different ground-state extraction strategies; from left to right they are: two-simRR using all t_{sep} (Fit-1), two-simRR using the largest 5 t_{sep} (Fit-2), two-sim using the largest 4 t_{sep} (Fit-3), and two-sim using the largest 3 t_{sep} (Fit-4). All fits yield consistent results, as would be expected if the excited-state contamination is well-described by the two-state model.

(with only one additional excited-state related element) to obtain the ground-state nucleon matrix elements using largest four source-sink separations. Fit-4 uses the same strategy as in Fit-3 but with only the largest three source-sink separations. Fig. 1 shows the bare matrix elements for a range of positive z for all three momenta; all four fits yield consistent results. The two-simRR analysis using t_{sep} as small as 0.54 fm (Fit-1) gives consistent results with the two-sim analysis using $t_{\text{sep,min}}$ of 0.81 fm (Fit-3), with approximately the same statistical errors after removing the excited-state contamination. Similar results are obtained by two other fits Fit-2 and Fit-4, except with larger uncertainty due to fewer three-point proton correlators. We use the fit with two-simRR with $t_{\text{sep,min}} = 0.72$ fm for our final analysis.

To obtain the nonperturbative renormalization factor, one needs to calculate the matrix elements of $\hat{O}(z, a)$ in a large-momentum quark state with point sources. The momentum dependence is studied with the z -component ranging from $p_z^R = 0$ to 3 GeV at off-shell mass $\mu_R = 2.3$ and 3.7 GeV. For $\mu_R = 3.7$ GeV, the renormalization factor changes appreciably in the small- p_z^R region, whereas

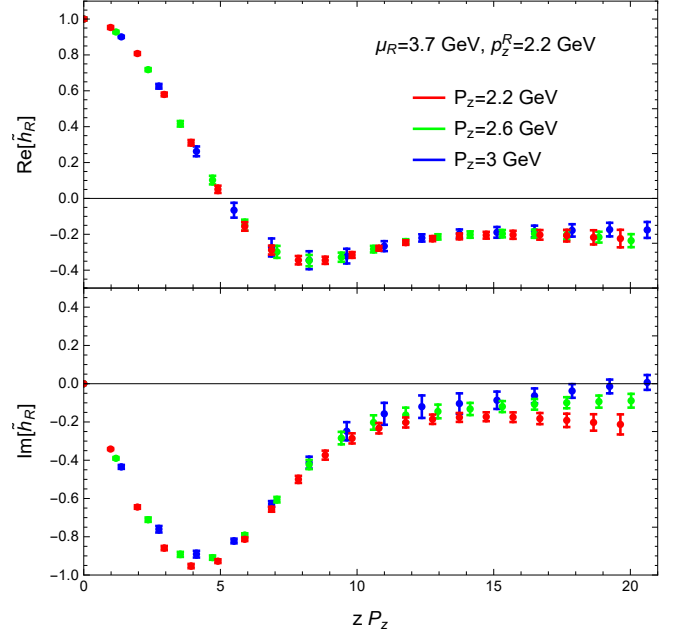

FIG. 2. The real (top) and imaginary (bottom) parts of the renormalized proton matrix elements as functions of zP_z , at renormalization scale $\mu_R = 3.7$ GeV, and $p_z^R = 2.2$ GeV.

at large p_z^R , it reaches a plateau. Similar behavior is observed in the $\mu_R = 2.3$ GeV case. We pick $p_z^R = 2.2$ GeV as our central value for the renormalization factor.

The renormalized isovector quark-helicity correlators as functions of zP_z are shown in Fig. 2 for $\mu_R = 3.7$ GeV, and $p_z^R = 2.2$ GeV, with the real part shown in the top panel and the imaginary at the bottom. The red, green, and blue colors indicate proton momenta of 2.2, 2.6 and 3.0 GeV, respectively. We normalize all the matrix elements with $\tilde{h}_R(P_z, z=0)$ and multiply the final result by $g_A = 1.275$. The nonzero long-range correlation in zP_z reflects the significant presence of small-momentum partons. The data indicate that the correlation approaches a near-constant value, and therefore, we use the “derivative” method proposed in our earlier work [25] to obtain the quasi-PDF:

$$\Delta \tilde{q}_R(x, P_z) = \int_{-z_{\text{max}}}^{+z_{\text{max}}} dz \frac{ie^{ixP_z z}}{x} \partial_z \tilde{h}_R(z, P_z). \quad (4)$$

Again $\partial_z \tilde{h}_R(z, P_z)$ is consistent with zero for $|z| > 15a$, and we vary z_{max} to estimate the error, which is small compared with other systematics.

We show in the top panel of Fig. 3 a comparison between the renormalized quasi-PDF at $P_z = 3.0$ GeV and the isovector quark helicity distribution resulting from the matching formula in Eq. 3 with proton-mass correction (see Ref. [12] for details on the de-convolution). The error bands are statistical only. The matching corrections suppress the distribution at mid x to large x , yielding a positive antiquark (negative- x region) helicity for $x < -0.1$. This is physically intuitive because match-

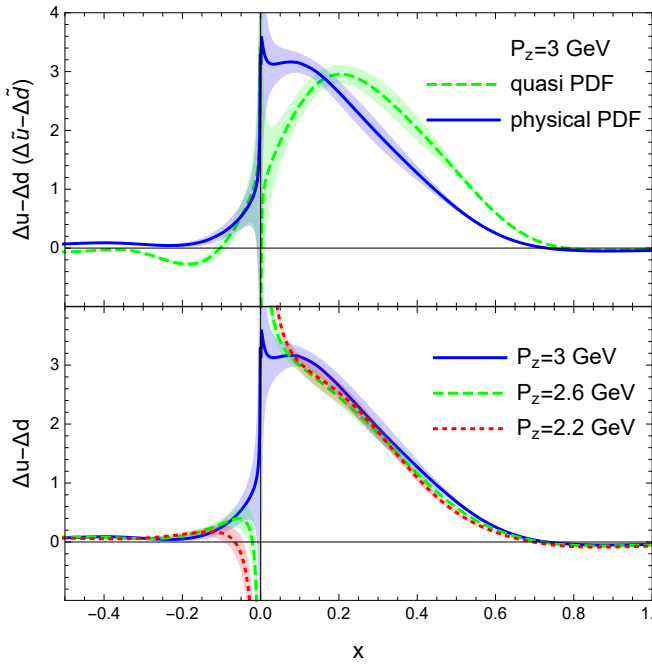

FIG. 3. The top panel is a quark helicity quasi-PDF in RI/MOM scheme at proton momentum 3.0 GeV and resulting physical PDF in $\overline{\text{MS}}$ at $\mu = 3$ GeV. The error bands are statistical. The bottom panel shows the matched physical PDFs from various proton momenta.

ing is in some sense boosting the finite-momentum quasi-PDF to an infinite-momentum one with proper renormalization, and boosting will in general move large- x partons to smaller x . In the bottom panel, we show a comparison between the helicity distributions extracted from different proton momenta. In the large- x region, the differences are small, indicating small higher-twist effects. However, the central values at small and negative x shift noticeably from 2.2 to 3.0 GeV, reflecting the change of the limiting behavior of the lattice correlation $\tilde{h}(z, P_z, a)$ at large zP_z shown in Fig. 2.

Our final isovector quark helicity distribution, obtained at the largest proton momentum of 3 GeV, is shown in Fig. 4. The statistical error (with the excited-state contamination subtracted based on two-state fits) is shown as the red band. The systematic uncertainty, shown combined in total with statistical one as the gray band in Fig. 4, is obtained partly by varying the scales in the NPR for $\mu_R \in \{2.3, 3.7\}$ GeV and $p_z^R \in \{1.3, 3\}$ GeV. The error from one-loop matching inversion is estimated by the second-order correction. The systematics associated with lattice spacing a (discrete action, mismatching in valence and sea fermions, and rotational symmetry violation, etc) and with finite volume effects are estimated to be conservatively about 8% and 5%, respectively, allowing a factor of 2-3 larger than the first-moment calculation itself in Ref. [40] to account for the unknown x -dependence and Lorentz-boost effect (see below). The target-mass correction from Ref. [24] is found to be neg-

ligible for all three nucleon momenta, again indicating small higher-twist contributions. Also shown in the figure are the phenomenological fits from NNPDFpol1.1 [2] and JAM [3]. The present calculation is consistent with experiment within 1σ in the large- x region. For x very close to 1, the calculation is in principle limited by the finite lattice spacing effect at large P_z , where the proton needs be resolved with a finer longitudinal scale because of Lorentz contraction. However, the consistency of data at small zP_z in Fig. 2 indicates that moderate P_z may be sufficient for an accurate result. For $x < 0.1$, the present calculation is limited by the accuracy of large- zP_z data. As in experiment, determining the small- x PDFs requires large-momentum hadrons.

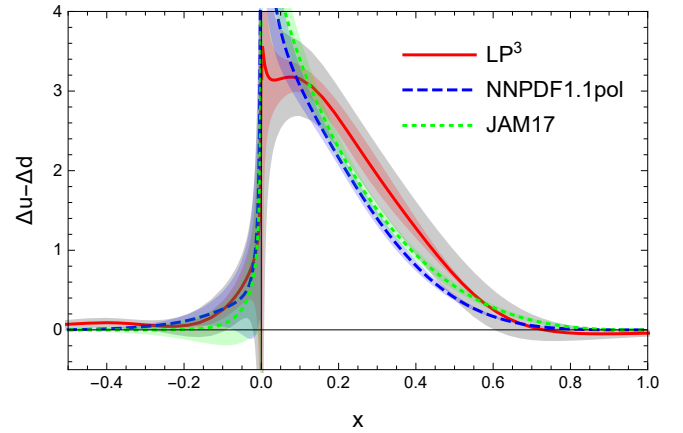

FIG. 4. The red line is the $\overline{\text{MS}}$ -scheme isovector quark helicity PDF at scale $\mu = 3$ GeV, extracted from LaMET at the largest proton momentum (3 GeV), compared with fits by NNPDFpol1.1 [2] and JAM [3]. The red band contains statistical error while the gray band also includes estimated systematics from finite lattice spacing, finite volume, higher-twist corrections, as well as renormalization scale uncertainties.

The present calculation shows the potential impact of lattice simulations combined with the LaMET approach in determining PDFs. The JLab 12-GeV program is well positioned to make large- x determinations of polarized and unpolarized parton distributions, which are extremely valuable to interpret large P_T events at the Large Hadron Collider. Lattice calculations at 10% level will already be very useful in deciding the large- x behavior, cross-checking with the experimental data.

To summarize, we report a state-of-the-art isovector quark helicity distribution using lattice-QCD simulations at physical pion mass with proton momentum as large as 3 GeV. With high statistics, we combined multi-state analysis and multiple source-sink separations to remove excited-state contamination from our analysis; its error is reflected in our statistical uncertainty. We renormalize the nucleon matrix element using the nonperturbative RI/MOM renormalization, and perform the LaMET one-loop matching to convert quasi-distribution to physical distribution in the $\overline{\text{MS}}$ scheme. An estimate of the sys-

tematic uncertainty introduced by the choice of scales in the nonperturbative RI/MOM renormalization and one-loop matching inversion, as well as finite lattice spacing and volume is included in the final analysis. Our final result is consistent with the global analyses done by NNPDF and JAM within theoretical errors. Future directions will be to investigate finer lattice-spacing ensembles and to reach even higher proton momenta, so that we can push toward smaller x in advance of upcoming experiments such as at the EIC.

ACKNOWLEDGMENTS

We thank the MILC Collaboration for sharing the lattices used to perform this study. The LQCD calculations were performed using the Chroma software suite [38].
