Abstract:

The nematic liquid crystal (LC) director field can contain defects that are both singular and nonsingular, but nonsingular defects with an integer winding number of the director are typically metastable because of their high energy. Here, we demonstrate topology-mediated generation and stabilization of nonsingular wall loops in a sandwich-type LC cell by combining a patterned substrate with a planar substrate. We implement a design which imposes a topological constraint on a singular disclination loop such that it irreversibly annihilates upon application of a field, and results in the generation of a stable nonsingular wall loop when the field is removed. Theoretical modelling agrees with experimental observations, providing insight into the wall generation mechanism and its stability. The concept to stabilize high energy structures through orientation-patterning-defined topological constraints extends our ability to control orientationally ordered matter.

The nematic liquid crystal (LC) is a phase in which the constituent rod-like molecules spontaneously orient along a single direction, referred to as the director. The nematic director field can accommodate defects that are either singular or nonsingular, characterized by the number of rotations of the director around the defect core [1, 2]. Singular defects can exist as lines or points, and have been studied from various perspectives, from testing topological theorems [3, 4] to utilizing them to modulate the local physical properties [5] or as templates for dopant materials [6-12].

In contrast to singular defects, nonsingular defects are much less explored. Nonsingular defects occur as spatially localized excitations in the director field, and have continuous structures that are topologically equivalent with a uniformly aligned nematic [2]. In a sandwich-type nematic cell with planar boundary conditions, nonsingular defects appear at the boundary of two topologically equivalent regions in the form of walls, with the director locally orienting perpendicular to the substrates [13-17]. However, the steep variation in the orientation makes them high energy such that wall loops formed at the isotropic-nematic phase transition shrink and disappear over time [13]. Also, the property of LCs to minimize their free energy creates a tendency for walls to split into lower energy disclinations (singular line defects) [6]. Consequently, the study of walls had been mainly

limited to those that appear only under an external field [18], offering little freedom in their control. While the growing interest in defects has led to various strategies for the control of disclinations, such as the inclusion of colloidal particles [3-4,19] and use of patterned substrates [6,20-22], little attention had been paid on actively controlling nonsingular defects.

In this letter, we present a strategy to stabilize arbitrarily-shaped wall loops in an achiral nematic LC through surface anchoring design of a sandwich-type cell. A combination of a uniform planar and a suitably patterned substrate generates a looped disclination, which upon application and cessation of an electric field, is converted into a stable wall loop. The conversion makes use of the local incompatibility in director topology so that regeneration of the singular disclination is suppressed although it has lower energy than the wall. The wall position is well reproduced by theoretical modelling, clarifying the underlying stabilization mechanism. Our approach enables selective stabilization of high energy defect structures, extending our control over orientationally ordered matter.

Figure 1 depicts the easy axis distributions to stabilize a circular wall loop. The easy axis on one substrate ("patterned substrate") is patterned such that the azimuthal angle,

$\varphi_p(r)$, is given by Eq. (1) in cylindrical coordinates, where r is the position along the radius from the pattern center:

$$\varphi_p(r) = -\frac{\pi}{r_0} r + \frac{3\pi}{2}, \quad 0 \le r \le \frac{3r_0}{2}. \tag{1}$$

The azimuthal angle changes by π over a distance of r_0, and extends to $3r_0/2$. Another substrate ("uniform substrate") is prepared to possess uniform orientation, and a sandwich cell is fabricated using the two substrates so that the easy axis of the uniform substrate is parallel to the region of 0 radian on the patterned substrate.

A ~8 μm-thick sandwich cell was prepared using two substrates coated with polyimide (JSR, AL1254) and photoalignment agent (DIC, LIA-03). The substrate with polyimide was rubbed unidirectionally, whereas the substrate with the photoalignment layer was patterned to possess the easy axis distribution of Fig. 1(a) using maskless photoalignment [22]. The photoalignment setup imprinted the local orientational easy axis over an area of 1,024 × 768 pixels, where each pixel size was ~ 1.3 × 1.3 μm^2. The pattern was digitized to 3° steps and imprinted with a light dosage of 0.3 μJ/pixel. After cell fabrication, a nematic LC (5CB, Merck) was injected into the cell in the isotropic phase, and observed at 30 °C using a polarizing optical microscope (POM, Nikon, LV100 POL).

Figure 2 (a) shows a schematic of the LC-filled cell. A nematic LC confined between two substrates with different easy axis directions twists in the bulk to minimize the elastic free energy [1]. Because 5CB is achiral, the director twists in the direction that reduces the twist angle. The twist angle distribution expected from the pair of substrates used is shown in Fig. 2(c), where the twist angle is kept below $|\pi/2|$ in all regions. At $r = r_0$, the twist angle changes discontinuously by π, and changes the twist direction from left ($r < r_0$) to right ($r > r_0$). The π jump in twist angle is accompanied by a singular disclination, and appears as a black line floating in the LC.

Figure 2(d-f) shows POM images of the sample with r_0 = 107 μm. Between crossed polarizers, light is transmitted where its polarization changes due to director twisting. The disclination loop appears as a thin dark line at approximately $r = r_0$, and is also observed without the analyzer. Insertion of a first order retardation plate (λ = 530 nm) shows that the twist sense is inverted at the defect, but there is no tilt induced in the director, since no significant change in birefringence occurs near the disclination.

Generally, disclinations possess a line tension and tend to shrink [1,24]. However, the easy axis on the patterned substrate is designed such that the elastic energy due to director

distortion increases with disclination shrinkage. That is, because the twist angle can only change discontinuously at the disclination, its displacement from position r_0 to $(r_0 - \Delta r)$ causes the twist inversion to occur at twist angles of $(\pi\Delta r/r_0 \mp \pi/2)$ instead of $\mp\pi/2$. This increases the twist component of the elastic energy, which is proportional to the square of the twist rate [1]. The disclination loop is stabilized where the free energy of the disclination relieved by shrinkage is balanced by the increase in the elastic energy [22] (see also SI Section 1).

After confirming the generation of a disclination loop, an electric field (1 kHz, 2.5 V) was applied between the substrates. The electric field reorients the director perpendicular to the substrates and untwists the director [1], causing the disclination to shrink and annihilate over time. When the field is removed after disclination annihilation, the disclination does not reappear, but a nonsingular wall loop is generated at $r \sim 1/2r_0$ (Fig. 2(h-j) and Supplementary Movie 1). The wall loop is stable and only disappears when the sample is heated into the isotropic phase, but upon reentering the nematic phase, the disclination reappears, implying that the configuration with the disclination has lower energy. The wall appears thicker than the disclination and can also be observed without the analyzer. Insertion of the retardation plate reveals a color change in regions separated

by the wall, implying again a large change in twist angle at the wall. On the other hand, the color changes inside the wall, implying that now there is an out-of-plane tilt deformation of the director.

The above observations allow us to interpret the disclination-to-wall transition mechanism as follows. Consider a cross-sectional area of the cell containing a section of the disclination that runs perpendicular to the plane (Fig. 2(a)). The topological properties of a line defect can be analyzed by taking a circular path around the disclination core and mapping the orientation along the path on a sphere representing all the possible orientation directions (i.e., order parameter space) [2]. Defects in LCs are also commonly characterized by their strength: it is the number of 2π rotations of the director along a circular path that surrounds the defect, and can take half-integers or integers. In a three-dimensional nematic, defects with half-integer strength can be continuously transformed into a defect of strength 1/2, and those with integer strength can be transformed into a uniformly aligned state with strength 0. Thus, the topological invariant, or charge, can only take two values, either 1/2 or 0 (in terms of defect strength), and must be conserved according to the following: 1/2 + 0 = 1/2 and1/2 + 1/2 = 0.

In Fig. 2(a), the disclination gives a contour on the order parameter space terminating at diametrically opposite points; it is a topologically stable singularity with charge 1/2. Because there is another defect with opposite strength on the other side of the loop (at $\theta = \pi$), shrinkage of the defect by the applied field causes the disclination to eventually annihilate and give a net defect strength of 0. When the field is removed, the most stable configuration would be to have the two disclinations repositioned at their initial positions (recall that this configuration is always obtained through thermal phase transition). However, because the director is now everywhere continuous and free of singularities, there is locally a topological incompatibility that prohibits the regeneration of disclinations. Instead of returning to a state with two defects of charge 1/2, the system is required to relax into a state with charge 0 everywhere, i.e., with 0 or integer defect strength.

Since shrinkage of the disclination loop causes the right-handed twist region (originally at $r > r_0$) to extend to below r_0, a configuration with strength 0 corresponds to one that is right-handed everywhere. On the other hand, the configuration with strength 1 corresponds to one that accommodates a wall with a 2π jump in twist angle [23,24]. A completely right-handed configuration would require the maximum twist angle to reach

$3\pi/2$ at $r = 0$ whereas, while the wall has high energy density and its energy is proportional to its length, the maximum twist angle can be reduced to $\sim|\pi|$, if it is accommodated at $r = r_0/2$, where the easy axes on the substrates are parallel [Fig. 2(g)]. Thus, there is a competition between wall shrinkage and minimization of director twist acting in opposite directions, similar to the case of the disclination. Stabilization of the wall occurs as a result of the LC relaxing into a topologically-allowed configuration with lowest energy.

We analyze the free energy landscape of the director configuration with a wall loop and show that there is indeed an equilibrium loop radius that minimizes the energy. We base our analysis on a model for the wall proposed by Turner [15], which describes the director distribution using an analytical function with no singularities (SI Section 2). The Turner distribution has been found to be a close approximation to that obtained by minimizing the free energy numerically [17]. A cylindrical coordinate system is employed, with the uniform and patterned substrates placed at $z = -d/2$ and $d/2$, where d is the cell gap. A LC with splay, twist, and bend elastic constants of K_{11}, K_{22}, and K_{33} fills the cell and accommodates a circular wall loop with center at the origin and radius r_w.

To satisfy the boundary conditions set by orientation patterning, we modify the Turner

distribution and use the following, $\mathbf{n}_{\mathrm{w}}(r, z)$, for a wall positioned at $r = r_{\mathrm{w}}$:

$$n_{\mathrm{w}x} = \cos\left\{\pi\cdot\left\{1+\left(-\frac{r}{r_0}+\frac{1}{2}\right)\cdot\tanh\left\{m\left(r-r_{\mathrm{w}}\right)\right\}\right\}\cdot\left(\frac{z}{d}+\frac{1}{2}\right)\right\}$$

$$n_{\mathrm{w}y} = \sin\left\{\pi\cdot\left\{1+\left(-\frac{r}{r_0}+\frac{1}{2}\right)\cdot\tanh\left\{m\left(r-r_{\mathrm{w}}\right)\right\}\right\}\cdot\left(\frac{z}{d}+\frac{1}{2}\right)\right\}\cdot\tanh\left\{m\left(r-r_{\mathrm{w}}\right)\right\}. \quad (2)$$

$$n_{\mathrm{w}z} = \sin\left\{\pi\cdot\left\{1+\left(-\frac{r}{r_0}+\frac{1}{2}\right)\cdot\tanh\left\{m\left(r-r_{\mathrm{w}}\right)\right\}\right\}\cdot\left(\frac{z}{d}+\frac{1}{2}\right)\right\}\cdot\mathrm{sech}\left\{m\left(r-r_{\mathrm{w}}\right)\right\}$$

The director changes its twist direction at $r = r_{\mathrm{w}}$ as well as orients perpendicular to the substrates, with a wall thickness defined by the parameter m (SI Section 3). Here we use the following for m, which minimizes the free energy for a parallel planar boundary condition [16]:

$$m = \frac{\pi}{d}\sqrt{\frac{K_{11}+K_{33}-2K_{22}}{3K_{22}+K_{33}}}. \quad (3)$$

In SI Section 4, we evaluate the topological charge of the wall in a single r-z plane using Eq. (2), and show that it is indeed different from the disclination.

We numerically calculate the Oseen-Frank free energy of LCs, F, using $\mathbf{n}_{\mathrm{w}}$ (SI Section 5) [1]. Figure 3 (a) plots F as a function of r_{w}, where d = 7.95 μm, and r_0 = 107.2 μm as in experiment, and K_{11} = 4.85 pN, K_{22} = 3.1 pN, K_{33} = 6.1 pN for 5CB [25]. F has a local minimum at r_{w} = 48.7 μm, which agrees with the experimental equilibrium radius at 49 μm. Note that the proposed mechanism yields an equilibrium radius that is always smaller

than $r_0/2$, where intuitively, the wall is likely to appear. In fact, Supplementary Video 1 shows a two-step transition for wall generation and stabilization, where the wall first appears at $r_0/2$ and then shrinks to the equilibrium position.

The validity of the model was investigated further by varying r_0 from 26.8 – 134 μm. Figure 3 (b) compares the experimentally measured and theoretically predicted wall radii (POM images shown in SI Section 6). For $r_0 > 50$ μm, experiment agrees well with theory, with the deviation between the two falling within 3%. For $r_0 = 40.2$ μm, the wall had an equilibrium radius of 15.2 μm, whereas theory predicted equilibrium at $r = 0$, i.e., the director configuration without the wall to have lower energy. While this discrepancy is believed to be a result of $\mathbf{n}_w$ not fulfilling the Euler-Lagrange equations, we note that the energy difference between director configurations with and without the wall approaches 0 at the crossover of the stable state, which makes both configurations equally stable and thus prone to small fluctuations. Overall, the model reproduces the phenomenon more than satisfactorily, validating the stabilization mechanism.

We also investigate the effect of varying r_0 and d on the wall stability. Fig. 3(c) shows relative stabilities of the director configuration with the wall to that without, where the

dashed line represents the crossover condition of the stable configuration. Clearly, increasing stability is predicted for larger r_0 and smaller d, which can be attributed to the fact that the wall has to move over a greater area for larger r_0, and, the director twist rate, and hence the elastic energy penalty upon wall shrinkage, increases for smaller d. The results also allow us to infer that a steep change in twist angle near the wall stabilizes it, since the energy rises quickly even for small shrinkage.

Finally, we extend our strategy to stabilize an arbitrarily-shaped wall loop. Figure 4 shows disclination and wall loops stabilized in the shape of our school logo. The wall appears approximately where the substrates have parallel orientation, and its stability increases with a steeper change in twist angle. Following this principle, we create four regions in the shape of the logo and obtain the easy axis distribution in each domain as numerical solutions to Laplace's equation. For domains labelled I, II, and III in the figure, the outer and inner boundary conditions are set to $(0, -\pi/2)$, $(\pi/2, 0)$, and $(0, 4\pi/9)$. The sample first shows a disclination loop approximately at the boundary of domains I and II. Upon applying and removing an electric field, the disclination annihilates and a wall loop appears approximately at the boundary of domains II and III [Fig. 4(c,d), see also SI section 7]. This demonstrates the versatility of our approach, allowing meaningful

symbols to be represented by stable walls.

In conclusion, we demonstrated a topology-mediated pathway for the generation of high-energy, nonsingular wall loops in a nematic LC. The study is distinct form other works in that a pure nematic LC with no inclusions is used in a planar cell structure, and the generated loop, which can be designed arbitrarily, is stable without a sustaining electric field. Other than motivating the search for designs to stabilize even higher energy defects, our work opens doors to detailed investigations of defect structure and dynamics [27], as well as its interaction with various dopants. Surface patterning allows positioning of the defect, which is usually not possible with colloid-induced defects, and thus is advantageous for potential applications of defects. Considering that steep changes in the director not only affects the elastic energy of the system, but also the dielectric and rheological properties, we anticipate the emergence of novel phenomena and applications through the investigation of defect-matter interactions in a controlled environment.
