We use self-consistent Hartree-Fock calculations performed in the full \( \pi \)-band Hilbert space to assess the nature of the recently discovered correlated insulator states in magic-angle twisted bilayer graphene (TBG). We find that gaps between the flat conduction and valence bands open at neutrality over a wide range of twist angles, sometimes without breaking the system’s valley projected \( C_2T \) symmetry. Broken spin/valley flavor symmetries then enable gapped states to form not only at neutrality, but also at total moiré band filling \( n = \pm p/4 \) with integer \( p = 1, 2, 3 \), when the twist angle is close to the magic value at which the flat bands are most narrow. Because the magic-angle flat band quasiparticles are isolated from remote band quasiparticles only for effective dielectric constants larger than \( \sim 20 \), the gapped states do not necessarily break \( C_2T \) symmetry and as a consequence the insulating states at \( n = \pm 1/4 \) and \( n = \pm 3/4 \) need not exhibit a quantized anomalous Hall effect.

Introduction.— A small relative twist between adjacent graphene layers produces a triangular lattice moiré pattern with a spatial periodicity that is inversely related to twist angle. It was noticed \[1\] some years ago that at a series of magic twist angles \( \theta \), the moiré pattern yields very flat low-energy bands that promise strong electronic correlations. This promise has now been realized thanks to recent experimental studies \[2\] of bilayers with accurately controlled twist angles that exhibit interaction-induced insulating ground states at moiré band \[2\] filling factors \( n = \pm p/4 \), where \( p = -3, \ldots, 3 \) is the total charge per moiré unit cell. The insulating states are flanked by superconducting domes \[3,4\]. This exciting discovery has inspired a flurry of theoretical work \[5,6\] directed toward achieving a more complete understanding of the insulating states and their superconducting satellites. Previous work on the insulating states has been based mainly on an indirect approach that starts by identifying effective lattice models for the flat moiré bands, and then combines these with generalized Hubbard models to address interaction phenomena. In this Letter we explore a different approach.

At small twist angles the electronic structure of twisted bilayer graphene can be accurately described using a continuous model \[2,39\] in which single-particle electronic states with a four-level spin/valley internal flavor degree-of-freedom are approximated by four-component envelope function spinors that specify \( \pi \)-orbital amplitudes on the bilayer’s four sublattices. The simplest version of the continuum model \[2\] adds a spatially periodic interlayer hopping term to isolated layer \( \pi \)-orbital Dirac models. This moiré band Hamiltonian is spin-independent, and its projections onto graphene’s two valleys are related by time-reversal symmetry. Up to an overall energy scale, its spectrum depends on a single twist-angle dependent parameter \( \alpha = w/\hbar v k_0 \) where \( w \approx 110 \) meV is an inter-layer tunneling amplitude, \( v \approx 10^6 \) m/s is the Dirac velocity, \( k_0 = 2K \sin(\theta/2) \) is the momentum separation between the Brillouin-zone (BZ) corners in different layers, and \( K \) is the single-layer BZ corner momentum magnitude.

The valley-projected moiré flat bands in TBG occur not singly, but in valence/conduction pairs connected by two symmetry-protected linear Dirac band crossings. Importantly the two Dirac points of weakly coupled bilayers carry the same chirality. This property implies \[13,40,41\] that the moiré flat bands can be described only by tight binding models with at the very least four orbitals per spin/valley flavor per moiré unit cell. Recent work \[42\] suggests that faithful descriptions of interaction physics using generalized Hubbard models may require the inclusion of at least eight bands per flavor, limiting

---

**FIG. 1:** Phase diagram of neutral bilayers as a function of Coulomb interaction strength, characterized by inverse dielectric constant \( \epsilon^{-1} \), and twist angle \( \theta \). (a) Insulating states (blue regions) appear for ever weaker interactions as the narrow-band magic angle regime near \( \theta \sim 1.1^\circ \) is approached. Above the magic angle, the bilayer’s Dirac points are gapped when the effective fine structure constant \( \alpha^* = e^2/\epsilon \hbar v k_0 \) exceeds \( \sim 0.4 \) (solid line), where \( v_k^* \) is the Dirac velocity of the twisted bilayer. \( (\rho_B^* \rightarrow 0 \) as the magic angle is approached \[2\].) For \( \epsilon^{-1} \gtrsim 0.05 \) remote band degrees of freedom play a role in determining the phase diagram details, enabling in particular insulating states that do not break \( C_2T \) symmetry (hatched region of the phase diagram). (b) \( C_2T \) - breaking order parameter \( \rho_B - \rho_A \) (i.e., sublattice polarization) and (c) global energy gap as a function of interaction strength \( \epsilon^{-1} \) for \( \theta = 1.1^\circ \) (blue solid line) and \( 1.5^\circ \) (red dashed line).
the motivation for approximate lattice models.

In this Letter we report on a study of the correlation induced insulator states in magic angle TBG that starts directly from the moiré band continuum model and accounts for the long-range of the Coulomb interaction between electrons. Our principle results are summarized in Fig. [1]. In this figure the largest values of interaction strength parameter $\epsilon^{-1}$ correspond to screening by a surrounding hexagonal boron nitride dielectric only. In practice interactions are sample dependent and always weakened by nearby gates. We find that gapped states occur at neutrality when the effective fine structure constant $\alpha^* = e^2/\epsilon_0\hbar v_D^*$ exceeds $\sim 0.4$ for twist angle $\theta$ above the magic value, and almost always for twists that are smaller. Here $v_D^*$ is the reduced Dirac velocity of the twisted bilayer which vanishes as the magic angle is approached [2]. We attribute the smaller value of the critical fine structure constant in twisted bilayer graphene than in the corresponding single-layer graphene ([43], indicated as black dashed line in Fig. [1(a)]) calculations to the non-uniform spatial distribution of flat band orbitals, which enhances interaction effects. As in single layer graphene ([43]), these gapped states break $C_2T$ symmetry and have non-zero Berry curvatures, whereas the the gapless states preserve $C_2T$ symmetry. For $n = \pm p/4 \neq 0$, gapped states are enabled by broken spin/valley flavor symmetries and occur over a much narrower range of twist angles. When the interaction strength is sufficiently strong, gapped states can be opened without breaking the $C_2T$ symmetry that protects band crossings when the Hamiltonian is projected onto the strongly correlated flat bands. This property is significant because it has implications for the occurrence of quantized anomalous Hall effects at band filings $n = \pm 1/4$ and $n = \pm 3/4$.

Mean field theory.—Our theoretical approach is guided by the experimental [4] discovery of insulating states in magic angle TBG that are naturally explained by broken symmetries that lift the four-fold spin/valley degeneracy of the band Hamiltonian, and do not require broken translational symmetry. In most cases the ground states of insulators can be described using Hartree-Fock mean-field theory. The difficulty in the TBG case compared to the familiar case of atomic-scale insulators, is that the Hamiltonian does not contain strong attractive potential terms within each unit cell that select particular high-weight atomic or ionic configurations. To understand the nature of the insulating states, we must perform unbiased Hartree-Fock calculations in the full [45] $\pi$-orbital Hilbert space, placing no restrictions on the flavor or position dependence of the model’s four-component envelope function spinors.

A typical self-consistent Hartree-Fock calculation result, for the point $\epsilon = 5$ and $\theta = 1.1^\circ$ marked by a red dot in Fig. [1(a)], is summarized in Fig. [2] which illustrates quasiparticle dispersion, topology, and $C_2T$ breaking order parameters, and in Table I in which the ground state energies of the non-interacting and interacting cases are partitioned into intralayer and interlayer tunneling and interaction contributions. The technical details of these calculations are described in the Supplemental Material. All energies are expressed relative to the energy of the non-interacting state in the absence of inter-layer tunneling, and a neutralizing background charge density is assumed. As shown in Fig. [2] we find separate self-consistent gapped solutions with and without $C_2T$ symmetry breaking. The $C_2T$ symmetry broken solution features moiré bands with well-defined non-zero Berry curvatures and sublattice polarizations $\rho_B - \rho_A$, and is lowest in energy in most regions of the phase diagram as shown in Fig. [1(a)].

In Table I we note that the ratio of the cost in intralayer tunneling energy, to the energy gain from inter-layer tunneling in the non-interacting ground state is $1:2$, the ratio that is obtained when inter-layer tunneling is treated as a weak perturbation. This observation is consistent with the property [2] that the first magic angle in twisted bilayer graphene is accurately predicted by perturbation theory. Secondly we observe that at neutrality both non-interacting and interacting ground states have almost uniform charge density, even though the flat band wavefunctions are spatially peaked near AA positions in the moiré pattern. The absence of a Hartree energy at neutrality is related to the moiré band Hamiltonian’s approximate particle-hole symmetry, and is quite distinct from what would be obtained if the Hilbert space were truncated to include only the lowest energy flat bands. Finally we note that the condensation energy of the gapped state, which we define as the difference between ground state energy and the expectation value of the Hamiltonian in the non-interacting ground state, is $\sim 117$ meV per moiré period and originates mainly from enhanced interlayer exchange energies. At this value of $\epsilon^{-1}$ and $\theta$, total energy minimization including interactions adjusts the ground state so as to enhance interlayer tunneling and interlayer exchange energies at a cost in the

TABLE I: Total energy per moiré unit cell at neutrality in units of meV calculated in the non-interacting (NI) and self-consistent Hartree-Fock (SCHF) ground states for $\theta = 1.1^\circ$ and $\epsilon = 5$. Gapped insulating states with and without broken $C_2T$ compete closely, differing in energy by less than 1 meV per moiré cell. Note that Hartree energies do not play an important role in selecting the broken symmetry state. Both intralayer and interlayer energies grow with the momentum space cut-off, but the difference in energy between non-interacting and interacting states converges.
FIG. 2: Properties of quasiparticles at \( n = 0 \). Only valley \( K \) states are shown. (a) Energy dispersion of the \( C_2 \) \( T \) breaking (blue) and \( C_2 \) \( T \) preserving (red) states at \( \theta = 1.1^\circ \) and \( \epsilon = 5 \). The dotted lines illustrate the non-interacting flat bands. The inset specifies the high symmetry lines in the moiré BZ (mBZ) along which the band energies have been plotted. (b) Berry curvature for lowest conduction band (upper) and the highest valence band (lower) of the broken \( C_2 \) \( T \)-symmetry solution. Features in these plots are related to avoided crossings between the flat conduction band and higher energy remote conduction bands. (c) Order parameters for \( C_2 \) \( T \) symmetry breaking as a function of the reciprocal lattice vector \( G \) magnitude. The segments marked by vertical dashed lines group \( G_s \) with same magnitude.

The \( C_3 \) symmetry guarantees Dirac points at both \( \kappa \) and \( \kappa' \) in the mBZ. We find that near magic angle \( C_3 \) is already broken at the weakest interactions we consider and that because of the flatness of the magic-angle bands, the Dirac point positions rapidly move close to \( \gamma \) where the bands are most dispersive. The band topology evolution with \( \theta \) and \( \epsilon^{-1} \) is sensitive not only to interactions, but also to the details of the non-interacting band model (see Supplemental Material and [13]). Unless otherwise specified, we have taken \( T_{AA}/T_{AB} = 0.8 \), where \( T_{AA} \) and \( T_{AB} \) are the continuum model’s intra-sublattice and inter-sublattice hopping parameters, to account for corrugation and strain effects [47]. Even though this choice gives a gap between flat bands and remote bands in the non-interacting limit, near the magic angle a small interaction strength is sufficient to pull the highest valence (lowest conduction) band down (up) in energy to touch the remote bands. The band topology at \( \epsilon = 5 \) is illustrated in Fig. 2(b) by plotting Berry curvature in the \( C_2 \) \( T \) broken state as a function of moiré band momentum. Because of the involvement of remote bands, \( C_2 \) \( T \) symmetry no longer guarantees degeneracies between the first conduction and valence bands [14, 40]. Breaking \( C_2 \) \( T \) symmetry does however lift degeneracies between flat and remote bands, and generates corresponding Berry curvature hot spots that are visible in Fig. 2(b). The difference in condensation energy between \( C_2 \) \( T \) breaking and preserving states is extremely small. It follows that near magic twist angles \( C_2 \) \( T \) symmetry breaking is not essential for gap formation at moderate interaction strengths.

We characterize states that do break \( C_2 \) \( T \) symmetry by performing a Pauli matrix expansion of mBZ averages of the non-local Fock exchange self-energy, defining

\[
A_m \sum_{\vec{k}} \langle \vec{k} + \vec{G}, i', l', s' \mid \Sigma^F \mid \vec{k} + \vec{G}, i, l, s \rangle = \sum_{ij} \Delta_{G,ij} \sigma_{s' i' j} \sigma_{s i j}^t,
\]

where \( A \) is the system area, \( A_m \) is the moiré unit cell area, \((i, j) = 0, \ldots, 3 \) are Pauli matrix labels, \((s' i') = A, B \) are sublattice labels and \((i' l') = t, b \) (top, bottom) are layer labels. (The role of self-energy terms that are off-diagonal in reciprocal lattice vector as \( C_2 \) \( T \)-breaking order parameters is discussed in the Supplemental Material.) The slow fall-off of the order parameter’s reciprocal lattice vector expansion in Fig. 2(c) reflects the spatial scale of quasiparticle wavefunction variation within the moiré unit cell. The largest symmetry-breaking self-energy terms are proportional to \( \sigma_{s i j}^t \) and \( \sigma_{s' i' j}^t \), i.e. they are layer independent mass terms that favor one sublattice over the other. (We have sought self-consistent solutions with large \( \sigma_{s' i' j}^t \) self-energies but find that they are not stable.) The Berry curvatures plotted in Fig. 2(b) are large near \( \gamma \), not near \( \kappa, \kappa' \), as they would be if the same self-energy were added to a weakly-coupled-layer band Hamiltonian at a larger twist angle. We find that the flat bands sometimes have non-zero Chern numbers [7].
implying that quantized anomalous Hall effects can occur \[19\] when band occupations are valley-dependent.

**Flavor symmetry breaking.**—Because interactions normally induce gaps between conduction and valence bands, which then remain relatively flat, states with spin/valley flavor dependent band occupancies can be insulating. For example at \(n = +p/4\), a state with the first conduction band occupied for \(p\) flavors and empty for the remaining flavors is metastable if the exchange-energy shift of the conduction band upon occupation \(U_X\) exceeds the conduction band width. A rough estimate based on non-self-consistent Hartree-Fock calculations (see Supplemental Material) yields \(U_X \approx 250 \text{meV}/e\), increasing slowly with twist angle. The flat band width, on the other hand, increases rapidly when the magic angle is exceeded, so that insulating states are restricted to the immediate vicinity of the magic angle. Fig. 3 illustrates the quasiparticle bands that emerge from a typical fully self-consistent mean-field calculation for a broken flavor symmetry insulator. In mean-field theory, coupling between flavors occurs only through the Hartree potential which is absent at neutrality and attractive at AA sites in the moiré pattern at negative band filling factors. It follows that the energies and wave functions of the Hartree-Fock quasiparticle states of one flavor depend only weakly on the band-fillings of the other flavors.

**Discussion.**—Guided by earlier work \[50\], we anticipate that there is generally an energetic preference (not captured in continuum models) for states in which opposite valleys are occupied equally. Insulating states at \(n = \pm 1/4\) and \(\pm 3/4\) must however break valley symmetry and are likely to be maximally valley polarized, which implies quantization of the anomalous Hall effect. It therefore follows from our calculations that quantized anomalous Hall effects in graphene bilayers can occur at quarter band fillings, but that it may not either because \(C_2T\) symmetry is not broken or because the Chern number happens to equal zero \[7\]. Indeed there is evidence \[7\] experimentally that some insulating states at the quarters are Chern insulators and some are not. Further experimental work that maps out how this behavior depends on twist angles and distances to gates will be necessary to make a detailed comparison with mean-filed theory. The important role of thermal and quantum fluctuations of the collective fields present in the insulating states will be discussed elsewhere.

Note added.—Three independent related papers[51–53] which appeared after submission of our work report related results from mean-field theory and are complimentary to this paper.

[45] In the continuum model single-electrons states are described by valley-dependent four-component envelope-function spinors that specify position-dependent projections onto π orbitals on each of the bilayer’s four sub lattices. In the full π-band Hilbert space any dependence on position consistent with the emergent moiré superlattice periodicity is allowed. In practice we expand the periodic part of the Bloch spinors at each momentum in the moiré Brillouin-zone in reciprocal lattice vectors, truncating at convergence.
